## Executive Summary

As part of the Coquitlam River Water Use Plan (LB1 WUP), a long-term adaptive management study is being conducted in the Coquitlam River to compare anadromous fish production under two experimental flow regimes. Fish population monitoring under the first flow regime (Treatment 1, dam release flows from $0.8-1.4 \mathrm{~m}^{3} / \mathrm{s}$ ) occurred from 2000 until the completion of the Coquitlam Dam seismic upgrade in October 2008, with the exception of 2001(8 years). Fish production under Treatment 2 (release flows from $1.1-6.1 \mathrm{~m}^{3} / \mathrm{s}$ ) was initially proposed to be monitored until 2017 ( 9 years). This has since been extended for an additional 6 years (ending 2023) to increase the level of confidence in the inferences drawn from the study in the lead-up to the Water Use Plan Order Review. The overall objective of the Lower Coquitlam River Fish Productivity Index Monitoring Program (COQMON-07) is to provide the information necessary to better understand the trade-offs between fisheries, domestic water and power generation. To do this, COQMON-07 was designed to evaluate the fisheries benefits of each flow regime by monitoring adult escapement, and smolt and fry outmigration of four anadromous species including Steelhead Trout (Oncorhynchus mykiss), Coho Salmon (Oncorhynchus kisutch), Chum Salmon (Oncorhynchus keta) and Pink Salmon (Oncorhynchus gorbuscha). Higher returns during 2007-2016 allowed Chinook Salmon (Oncorhynchus tshawytscha) escapements to be estimated as well. Since 2006, night snorkeling surveys have also been included in the monitoring program to provide estimates of late summer standing stocks of juvenile Coho and Steelhead. This report summarizes monitoring results for the 8 years during Treatment 1 (2000-2008) and the 12 years of Treatment 2 (2009-2020) for the four major study components of the COQMON-07: adult salmon escapement surveys, Steelhead redd counts, juvenile standing stock surveys, and smolt and fry outmigration trapping. For Coho and Steelhead, the primary metrics for evaluating the fisheries benefits of each flow regime are smolt production. For Chum and Pink, it is the number of outmigrating fry produced per adult spawner. The evaluation also includes survival between various freshwater life-stages, fish size and habitat use. Adult abundance is given limited importance because of the large role that ocean survival plays in the number of salmon and Steelhead Trout returning to the Coquitlam River.

The primary emphasis of this report is on fall standing stock, smolt and fry outmigration, Steelhead escapement in 2021, and the 2020 escapement for Chum, Pink, Coho and Chinook salmon. Summaries of all data years for each species and life stage are presented and discussed as well. Estimates of adult escapement, late summer juvenile standing stocks and egg-to-smolt survival estimates should be considered preliminary and will change as additional observer efficiency data are accumulated in future years. Note that within this report, the precision of estimates represents the $95 \%$ confidence intervals or $95 \%$ credible intervals, the equivalent form for estimates relying on Bayesian statistics.

## Coho

An estimated 10,410 Coho adults returned to the Coquitlam River study area in 2020 and continues the trend of higher returns 2010 onward. As with past year, we are unable to estimate precision due to insufficient observer efficiency data. The 2021 late summer standing stock fry estimate was $28,049 \pm 29 \%$ based on night snorkel surveys, which was at the low end of the
range of previous years (18,405-91,367 fry), and below average for Treatment 2 (55,232 fry). During the spring of 2021, $9,446( \pm 7 \%)$ Coho smolts originating from mainstem habitats outmigrated past the lowermost trapping site. This is above the mean for Treatment $2(7,822$ smolts) but still less than the maximum for Treatment 1 ( 11,036 smolts) and Treatment 2 ( 10,953 smolts). An additional 1,582 smolts outmigrated from the four constructed off-channel habitats above RST2.

Using the combined Coho smolt yield from mainstem and off-channel habitat as the primary measure of freshwater carrying capacity, there was no significant difference in mean smolt freshwater production between Treatment 1 and Treatment 2 (mean: 12,949 and 11,651 smolts, respectively; 2 -tailed t -test $p=0.28$ ). When using only smolt yield from the mainstem of the Coquitlam River, which we consider a better indicator of treatment effects, there was a near significant difference between Treatment 1 and 2 (mean: 6,173 and 8,104, respectively; 2-tailed t-test $p=0.07$ ), even though mean yield increased $31 \%$. Note that while this does not technically meet the criteria that the probability the difference was due to chance was less than $5 \%$ ( $\mathrm{p}<$ 0.05 ), the value of the results are in the magnitude of the change and the still high likelihood that the results are not due to change. Maximum smolt yield was similar during each treatment period but minimum yield was lower and occurred more frequently during Treatment 1 than during Treatment 2 . This suggests that freshwater carrying capacity was not necessarily increased by Treatment 2, rather, that under Treatment 2 there were fewer low production years.

We are uncertain how much the change in Coho smolt yield was due to Treatment 2 flows, adult escapement or other regional factors that occurred over a similar time. Note that MON-7 uses a Before-After (BA) study design, which relies on the assumption the change in smolt yield is primarily the result of the flow treatments. For Coho, the moderate effect of adult escapement on smolt abundance and the rise in smolt yield in other watersheds raises the possibility that the increase was primarily the result of higher escapement rather than from the flow treatment. There is also some indication that ramping related stranding reduced fall fry abundance. The index of ramping related stranding is primarily a result of the number of Coho fry stranded through the June rampdowns during Treatment 2. As a consequence, the extent of the June rampdowns has been reduced for the last 2 years.

## Steelhead

In 2021, 214 unique redds were counted, which we used to estimate the total escapement of 357 Steelhead. This was near the mean for the 2005-2020 monitoring period (mean: 387
Steelhead). Redd counts suggests that Steelhead escapements during 2005-2021 ( 24 to 80 adults $/ \mathrm{km}$, or $37,000-149,000$ eggs $/ \mathrm{km}$,) were above that necessary to seed available juvenile habitat based on stock and recruitment data for the Keogh River (Ward et al. 1993), a wellstudied coastal stream, and based on our preliminary stock-recruitment analysis from the Coquitlam River. The late summer standing stocks estimates of Steelhead fry, age 1+ and 2+ parr for 2021 was $21,743 \pm 29 \%, 7,492 \pm 32 \%$ and $4,149 \pm 45 \%$, respectively. Smolt yield for the mainstem upstream of the lowermost trap (RST2) was $5,809 \pm 16 \%$ in 2021, which is within the study precision target.

Mean Steelhead smolt yield for the Coquitlam River mainstem increased $29 \%$ between Treatment 1 and Treatment 2 (mean: 3,701 and 4,778 smolts, respectively) and was significantly different (2-tailed t-test, $p<0.02$ ). This was almost entirely a product of increased smolt yield from reach 4, which increased $110 \%$ between Treatment 1 and 2 (mean: 925 and 1,938 smolts, respectively; 2 -tailed t-test, $p<0.01$ ). As well, abundance in reach 4 has been at least two-fold higher than during Treatment 1 in all but one year since 2009. For reaches 2 and 3, there was no significant change in smolt yield between Treatment 1 and 2 ( $-6 \%$ and $-8 \%$ change, respectively; 2 -tailed t-test, $p>0.8$ ).

Similar to Coho, we are uncertain whether a change in Steelhead production was due to Treatment 2 flows or other regional factors that occurred over a similar time. For the egg-to-fall fry period, the Ricker stock-recruitment analysis suggested a low influence of flow treatment but since no model described more than $23 \%$ of fall fry abundance, none of the variables had a large effect. For the fall fry-to-fall age-1 parr period, three models, including one with flow treatment had high support, and also explained the majority of the variance in fall age- 1 parr abundance. While this provides some support of a flow treatment effect, the model indicated Treatment 2 decreased parr abundance.

## Chum

An estimated 48,020 Chum adults returned to the Coquitlam River study area in 2020, which is at the upper end of the range for the monitoring period. As with the past year, we are unable to estimate precision due to insufficient observer efficiency data. In 2021, 4.9 million $\pm 5 \%$ Chum fry outmigrated past the lowermost trap. This is within the range for Treatment 2 (range: 1.9-12.7 million fry) and above the range for Treatment 1 (0.8-3.4 million fry). Egg-to-fry survival ranged from $3.7 \%-26.8 \%$, and averaged $10.0 \%$ during Treatment 1. Egg-to-fry survival during Treatment 2 averaged $22.7 \%$ and ranged from $12 \%-40 \%$. Some or all our survival estimates could be biased high as they exceed the published values for Pacific Northwest streams (Bradford 1995). Survival estimates may be better interpreted as an index, only comparable within the Coquitlam River Monitoring Program. Mean survival was significantly higher during Treatment 2 then during Treatment 1 (2-tailed t -test $p=0.01$ ). Stock-recruitment analysis also suggests that Treatment 2 likely increased fry production compared with Treatment 1. These findings could change as we further refine the Chum escapement model as well as with further comparisons with other rivers. Chum salmon returns to Coquitlam River were greatly improved in 2002-2020 compared to escapements in years prior to the implementation of the Treatment 1 flow regime in 1997.

## Pink

2020 was an 'off-year' for Pink spawning in the Coquitlam River. No estimates for adult escapement in 2020 or fry outmigration in 2021 is provided in this report. Fry yields during Treatment 2 have been up to 20 -fold higher than Treatment 1 and mirrors the significant changes in fry yield in the Cheakamus River since 2006. Egg-to-fry survival ranged from 5.1\%-9.7\% up to 2009 , which was comparable to reported values for other streams and potentially biased high survival rates of $24 \%-48 \%$ for the 2011-2015 broods. The good fit of the linear adult-to-fry stock-recruitment relationship including all Treatment 1 and 2 years $\left(\mathrm{R}^{2}=0.87\right)$ or only those years with comparable adult escapement $\left(R^{2}=0.90\right)$ suggest that adult escapement was the single largest driver of fry abundance and that fry abundance was minimally affected by the availability of spawning habitat. With only two run-years under Treatment 2 conditions at comparable escapement levels to Treatment 1, between-treatment comparisons are weak. For years with comparable escapements, there was also no significant difference in egg-to-fry survival. If future escapement continues at the lower levels similar to Treatment 1, additional monitoring may improve our ability to assess whether productivity differs between Treatments 1 and 2.

## Chinook

The Chinook escapement estimate for 2020 is 645 spawners. Escapement for 2007-2019 ranged from $360-8,000$ adults, and was likely less than 300 adults prior to this period. The highest Chinook escapement occurred in 2010 ( 8,018 adults). In 2023, too few Chinook juveniles were captured in downstream trapping to estimate the number outmigrating out of the Coquitlam River.

## COQMON-07 Status of Objectives, Management Questions and Hypothesis after

 Year 21 of Treatment 1 and 2| Primary Objective | Management Question | Management Hypothesis | Year 21 Status |
| :---: | :---: | :---: | :---: |
| To determine the fisheries benefits associated with the two test flows : <br> Treatment 1 -2FVC <br> Treatment2 - STP6 | Has juvenile rearing capacity of the Coquitlam River changed as a result of flow treatments for Coho and Steelhead? | $\mathrm{H}_{01}$ - Coho smolt production does not differ between Treatment 1 and 2 | $\mathrm{H}_{01}$ - possibly rejected. Possibly reject if based only on change in Coquitlam River smolt production. <br> Unclear of the effect of flow treatment on increased production. Section 6.1 |
|  |  | $\mathrm{H}_{0}$-Steelhead smolt production does not differ between Treatment 1 and 2 | $\mathrm{H}_{0}$ - possibly rejected. <br> Reject if based only on change in Coquitlam River smolt production. <br> Unclear of the effect of flow treatment on increased production. Section 6.2 |
|  | Has Chum and Pink juvenile productivity changed as a result of flow treatments in the Coquitlam River? | $\mathrm{H}_{03}$-Each adult Chum produced the same fry yield during Treatment 1 and 2. Stock-recruitment relationships unchanged | $\mathrm{H}_{03}$ - possibly rejected. High support of a treatment effect. <br> Section 6.3 |
|  |  | $\mathrm{H}_{04}$-Each adult Pink produced the same fry yield during Treatment 1 and 2. Stock-recruitment relationships unchanged. | $\mathrm{H}_{04}$ - status uncertain Insufficient data for between treatment comparison. No indication of habitat limitation under high Treatment 2 escapement levels. Section 6.4 |

Table 2.1 Water column visibility ( m ) at permanent measurement points at index sites A-E and surveyor 'guesstimates' of observer efficiency for Chum salmon (see Section 2.1.2) during surveys of the Coquitlam River for the 2020 brood year.

Table 2.2 Averages and absolute ranges for observer efficiency estimates (proportion of live salmon present that are visually detected) derived from mark-recapture experiments, and subjective 'guesstimates' of observer efficiency made by the survey crew for the same surveys during which the mark-recapture experiments occurred (see Section 2.1.2).

Table 2.3 Annual escapement estimates for Chum, Pink, Coho and Chinook salmon for the years 2002-2016 and 2018-2020. Also included are the mean abundance estimates during Treatment 1 (2002-2008) and Treatment 2 (2009-2020). ................................................................................. 21

Table 2.4 Adult spawning distribution by habitat type during Treatment 1 and 2, and the 2008 transition year. Treatment 2 flows were initiated October 22, 2008. Proportions shown are calculated based on counts of actively spawning fish only, during surveys when all five index sites were completed. $\mathrm{M} / \mathrm{S}=$ mainstem, $\mathrm{NOC}=$ natural off-channel, $\mathrm{OCR}=$ off-channel restoration site, and OC $=$ off-channel sites combined.

Table 2.5 Estimated average proportion of Chum, Pink, Coho and Chinook salmon spawning populations present at each index site (A-E) and at non-index (NI) sites during 2002-2016 and 2018-2020.

Table 3.1 The start and end date for Steelhead surveys, and the mean, minimum and maximum discharge ( $\mathrm{m}^{3} / \mathrm{s}$ ) in Coquitlam River at Port Coquitlam during surveys for the years 2005-2021 (Water Survey of Canada station 08MH002).

Table 3.2 Annual estimates of the total number of redds, redd $/ \mathrm{km}$, and the estimated number and density of female spawners, eggs, total escapement based on 1.2 females/redd, 3700 eggs/female and 2 spawners/redd. Peak counts represent the highest count of adults per year.

Table 3.3 Proportion of redds in reaches 2-4 of the Coquitlam River since redd surveys began in 2005.33

Table 3.4 Survey dates with raw counts of Steelhead redds, estimated new redds, and live adult counts for all surveys during 2021. Estimated new redds includes the sum of the raw count and the estimated number of redds that were constructed and then obscured by substrate movement prior to a scheduled survey, based on a redd survey life model. Appendix 3.3 lists this for all years.

Table 5.1 Start and end dates of trap operation, trapping season length, trapping days and percent season trapped for the 202146

Table 5.2 Summary of estimated smolt numbers and densities by species in 2021 for four offchannel sites, for reaches 2-4 of the Coquitlam River mainstem, and for the total Coquitlam River mainstem including and excluding the off-channel sites.48

Table 5.3 Differences in capture efficiency (proportion of marked smolts that were recaptured) for Coho and Steelhead from off-channel sites and the Coquitlam River mainstem at three rotary screw traps (RSTs) sites in the Coquitlam River mainstem in 2021. Stratified marking periods were pooled prior to testing (see Equation 5.1). Equal capture efficiency for mark groups was tested using Fisher's exact test. $\mathrm{P}<0.05$ indicates a significant difference in capture efficiency.

Table 5.4 Summary of estimated numbers of Coho, Steelhead and Chum smolts passing the three RST trapping locations (not reach estimates) in the Coquitlam River mainstem in 2021. Mark group indicates the location where fish were initially captured and marked. Also shown are numbers of marked (M), recaptured (R) smolts, unmarked captures (U) and estimated capture efficiencies (R/M).

Table 5.5 Captures of Chinook and Coho fry, Steelhead parr and Sockeye/Kokanee during 2021 at RST 2-4. 56

Table 6.1 Comparison of mean smolt yield, standard deviation (SD) and number of annual estimates ( N ) during Treatment 1 and Treatment 2 in the Coquitlam River including the p -values for the two-tailed t tests and percent change in mean abundance between Treatment 1 and 2. Only annual estimates for cohorts that reared exclusively under either Treatment 1 or Treatment 2 conditions were included. For Coho, this includes 2000-2008 for Treatment 1 and 2010-2021 for Treatment 2.

Table 6.2 Comparison of alternative Ricker stock-recruitment model predicting Coho smolt abundance as a function of adult abundance. Mean covariate effect denote the mean proportion of the total effect due to the covariate as well as the direction of the effect. $\mathrm{R}^{2}$ is the proportion of observed variance in log fry abundance predicted by the model, and $\triangle \mathrm{DIC}$ is the difference in the deviance information criteria for each model relative to the model with the lowest value (the best model). This includes the 2002-2019 brood years. Shaded rows indicate models with high model support ( $\Delta \mathrm{DIC}<2$ ). 68

Table 6.3 Comparison of alternative Ricker stock-recruitment model predicting Coho smolt abundance as a function of adult abundance. Mean covariate effect denote the mean proportion of the total effect due to the covariate as well as the direction of the effect. $R^{2}$ is the proportion of observed variance in log fry abundance predicted by the model, and $\Delta \mathrm{DIC}$ is the difference in the deviance information criteria for each model relative to the model with the lowest value (the best model). This includes the 2008-2019 brood years. Shaded rows indicate models with high model support ( $\Delta \mathrm{DIC}<2$ ).

Table 6.4 Comparison of alternative Ricker stock-recruitment model predicting Coho fall fry abundance as a function of adult spawner abundance. Mean covariate effect denote the mean proportion of the total effect due to the covariate as well as the direction of the effect. $\mathrm{R}^{2}$ is the proportion of observed variance in log fry abundance predicted by the model, and $\Delta \mathrm{DIC}$ is the difference in the deviance information criteria for each model relative to the model with the lowest value (the best model). This includes the 2005-2020 brood years. Shaded rows indicate models with high model support ( $\Delta \mathrm{DIC}<2$ ).

Table 6.5 Comparison of mean smolt yield, standard deviation (SD) and number of annual estimates (N) during Treatment 1 and Treatment 2 in the Coquitlam River including the p -values for the two-tailed $t$ tests and percent change in mean abundance between from Treatment 1 to 2 . Only annual estimates for cohorts that reared exclusively under either Treatment 1 or Treatment 2 conditions were included. For Steelhead, this includes 2000-2008 for Treatment 1 and 20122020 for Treatment 2.

Table 6.6 Comparison of alternative Ricker covariate stock-recruitment model predicting Steelhead fall fry abundance as a function of adult abundance. This includes the 2006-2021 brood years. Shaded rows indicate models with high support ( $\Delta \mathrm{DIC}<2$ ).

Table 6.7 Comparison of alternative Ricker covariate stock-recruitment model predicting Steelhead fall age-1 parr abundance as a function of fall fry. This includes the 2006-2020 brood years. Shaded rows indicate models with high support ( $\Delta \mathrm{DIC}<2$ ).

Table 6.8 Model performance of Chum egg-to-fry survival for 2002-2020 brood years by each of the explanatory variables evaluated using, linear ( $\mathrm{r}^{2}$ ), Akaike information criterion (AIC), and the distance from the lowest AIC value ( $\triangle \mathrm{AIC}$ ). AIC include the penalty for the number of parameters at each sample size. Shading marks the model(s) with the most support based on $\Delta \mathrm{AICc}$.

Figure 4.2 Estimates of juvenile standing stock, and $95 \%$ confidence intervals by species and age class in Coquitlam River during 2006-2021. Estimates were derived from night snorkeling counts with the exception of 2011 Steelhead (0+), which were based on electrofishing. Bar colour indicates cohorts that were reared entirely under Treatment 1 flows (red), Treatment 2 (green) or both (blue).

Figure 4.3 Length-frequency histogram (proportion of total catch less < 80 mm forklength) for Steelhead fry captured by electrofishing and counted during snorkeling in the Coquitlam River averaged for 2008-2010,2012-2019 and 2020 (data pooled for all sites). 2011 is also shown for electroshocking as an example of a year with considerable shift towards small sized fry.

Figure 5.1 Map of the Coquitlam River showing constructed off-channel habitat sites, mainstem reach breaks and the locations of mainstem rotary screw traps (RSTs). ...................................... 45

Figure 5.3 Daily catches of Coho smolts at downstream weirs in four off-channel sites (pooled data) and at three rotary screw trapping locations in the Coquitlam River mainstem in 2021. See Table 5.1 for start and end dates for individual trapping sites.

Figure 5.4 Daily catches of Steelhead smolts at downstream weirs in three off-channel sites (pooled data) and at three rotary screw trapping locations in the Coquitlam River mainstem in 2021. See Table 5.1 for start and end dates for individual trapping sites.

Figure 5.5 a-b Areal density of Coho and Steelhead smolt (smolts/100m2) in four constructed off-channel habitats along the Coquitlam River and for all four combined (Total) previous to Treatment 1 (1996-2000), Treatment 1 (2002-2008), when smolt cohorts reared under both treatments (2009) and Treatment 2 (2010-2021). Years with zero fish represent those when the off-channel habitats were not in operation or were not monitored.

Figure 5.6 Mean daily flows in Coquitlam River at Port Coquitlam during the smolt and fry trapping period in 2021. (Water Survey of Canada, stn. 08MH002). The maximum discharge for operating the smolt traps is shown by the red line $\left(20 \mathrm{~m}^{3} / \mathrm{s}\right)$ and for the fry trap by the blue line ( $12 \mathrm{~m}^{3} / \mathrm{s}$ ).

Figure 5.7 Daily catches of Chinook fry, Chum fry, Coho fry, Pink fry, Steelhead parr and Sockeye smolts at the RST2 trapping site in Reach 2 in the Coquitlam River in 2021. See Table 5.1 for start and end dates of downstream trapping.

Figure 5.8 Length-frequency histogram for unmarked Steelhead captured in the Coquitlam River in 2020 (data pooled for all trap sites).

Figure 6.1 Monthly discharge statistics for the Coquitlam River during Flow Treatment 1 (20002008) and Treatment 2 (2009-2021) measured at Port Coquitlam (Water Survey of Canada, stn. 08MH141) including monthly mean and minimum discharge as well as the coefficient of variation in monthly mean discharge.

Figure 6.2 Annual Coho smolts density for four constructed off-channel habitats connected to the Coquitlam River. The colours of the bars reflect the flow treatment period of the cohort outmigrating during that year: pre-Treatment (purple), Treatment 1(red), both treatment conditions (teal), Treatment 2 (green).

Figure 6.3 Annual Coho smolts yield and $95 \%$ confidence intervals for the 7.5 km study section of the Coquitlam River mainstem as well for individual reaches 2-4. The colours of the bars reflect the flow treatment period that cohorts were reared under: Treatment 1(red), both treatment conditions (blue), Treatment 2 (green). 65

Figure 6.4 Mean Coho smolt yield and $95 \%$ confidence intervals for Treatment 1 and Treatment 2 for the 7.5 km study section of the Coquitlam River mainstem and in reaches 2-4. Only annual
estimates for cohorts that reared exclusively under either Treatment 1 or Treatment 2 conditions were included. For Coho, this includes 2002-2008 for Treatment 1 and 2010-2021 for Treatment 2. 66

Figure 6.5 Average effect size and $95 \%$ confidence intervals of the change in smolt yield from Treatment 1 to 2 for Coho for the 7.5 km study section of the Coquitlam River mainstem (red) and for individual reaches 2-4 (blue). For Coho, this includes smolt estimates from 2000-2008 for Treatment 1 and 2010-2021 for Treatment 2.

Figure 6.6 Mean percent change in Coho smolt yield and 95\% confidence intervals from Treatment 1 (2000-2008) to Treatment 2 (2010-2018) in mainstem habitats in the Coquitlam River and control streams (Alouette and Keogh rivers, and Sakinaw Creek) with including all streams (Controls) or excluding the Alouette River (Controls_no_Alouette). This includes smolts estimates for cohorts that reared entirely under only Treatment 1 or 2, including 20002008 for Treatment 1 and 2010-2018 for Treatment 2. Note that Alouette and Sakinaw data sets did not included all years.

Figure 6.7 Fit of Ricker adult-to-smolt stock-recruitment covariate model for the Coquitlam River during Treatment 1 and 2 years (2002-2019 brood years) using the number of Coho fry stranded in May-July as the covariate, the model with the highest model support (lowest DIC value). Upper left pane shows the best fit line for the relationship between spawners and smolts, and model fit $\left(\mathrm{R}^{2}\right)$. The lower right pane shows the relative influence of the covariate across years.

Figure 6.8 Fit of the Base Ricker adult-to-smolt stock-recruitment model (no covariates) for the Coquitlam River during Treatment 1 and 2 years (2002-2019 brood years).

Figure 6.9 Mean Coho fall fry abundance and $95 \%$ confidence intervals during Treatment 1 (2006-2008) and Treatment 2 (2009-2021) for the 7.5 km study section of the Coquitlam River mainstem.

Figure 6.10 Fit of Coho adult-to-fall fry Ricker covariate model using number of the proportion of days in August with flows greater than $5.4 \mathrm{~m}^{3} / \mathrm{s}$ as the covariate for the Coquitlam River during Treatment 1 and 2 years (2005-2020 brood years). The upper-left panel shows the best fit line for the relationship between spawners and smolts, and model fit ( $\mathrm{R}^{2}$ ). This model shifts the stock-recruitment curve each year based on the number of stranded Coho fry salvaged following ramping events March-September. The vertical dashed lines show the covariate offset due to the covariate. 72

Figure 6.11 Fit of Coho adult-to-fall fry Ricker covariate model using number of fish stranded as the covariate for the Coquitlam River during Treatment 1 and 2 years (2005-2020 brood years). The upper-left panel shows the best fit line for the relationship between spawners and smolts, and model fit ( $\mathrm{R}^{2}$ ). This model shifts the stock-recruitment curve each year based on the number of stranded Coho fry salvaged following ramping events March-September. The vertical dashed lines show the covariate offset due to the covariate. 73

Figure 6.12 Annual Steelhead smolts yield and $95 \%$ confidence intervals for the 7.5 km study section of the Coquitlam River mainstem as well for individual reaches 2-4. The colours of the bars reflect the flow treatment period that cohorts were reared under: Treatment 1(red), both treatment conditions (blue), Treatment 2 (green).

Figure 6.13 Mean Steelhead smolt yield and $95 \%$ confidence intervals for Treatment 1 and Treatment 2 for the 7.5 km study section of the Coquitlam River mainstem and in reaches 2-4. Only annual estimates for cohorts that reared exclusively under either Treatment 1 or Treatment 2 conditions were included. This includes 2002-2008 for Treatment 1 and 2012-2020 for Treatment 2. 76

Figure 6.14 Average effect size and $95 \%$ confidence intervals of the change in smolt yield from Treatment 1 to 2 for Coho and Steelhead for the 7.5 km study section of the Coquitlam River mainstem (red) and for individual reaches 2-4 (blue). This includes 2002-2008 for Treatment 1 and 2012-2020 for Treatment 2.

Figure 6.15 Average percent change in Steelhead smolt yield and $95 \%$ confidence intervals from Treatment 1 (2000-2008) to Treatment 2 (2010-2018) in mainstem habitats in the Coquitlam River and Alouette River. This includes 2002-2008 during Treatment 1 and 20122018 during Treatment 2. Note that for the Alouette River, estimates were only available during Treatment 2 up to 2014.

Figure 6.16 Fit of Ricker stock-recruitment model to adult-to-smolt abundance for the Coquitlam River for the 2005-2018 brood years.

Figure 6.17 Average abundance and $95 \%$ confidence limits for Steelhead fry, age-1 parr and age- 2 parr during Treatment 1 and 2 in reaches $2-4$ of the Coquitlam River. The start of Treatment 2 for Steelhead fry, age-1 parr and age-2 parr is 2009, 2010 and 2011; respectively. 79

Figure 6.18 Estimates of juvenile standing stock, and $95 \%$ confidence intervals by species and age class in Coquitlam River during 2006-2021. Estimates were derived from night snorkeling counts with the exception of 2011 Steelhead (0+), which were based on electrofishing. Bar colour indicates cohorts that were reared entirely under Treatment 1 flows (red), Treatment 2 (green) or both (blue).

Figure 6.19 Fit of Ricker adult-to-fall fry covariate model to adult-to-fall fry using June mean discharge as the covariate for the Coquitlam River during Treatment 1 and 2 years (2006-2020 brood years). The upper-left panel shows the best fit line for the relationship between spawners and smolts, and model fit $\left(\mathrm{R}^{2}\right)$. This model shifts the stock-recruitment curve each year based on mean June discharge at the Port Coquitlam gauge. The vertical dashed lines show the offset due to the covariate. 81

Figure 6.20 Fit of Ricker fall fry-to-fall age-1 parr covariate model using days during September with flows greater than $5.4 \mathrm{~m}^{3} / \mathrm{s}$ as the covariate for the Coquitlam River during Treatment 1 and 2 years (2006-2020 brood years). The upper-left panel shows the best fit line for the relationship between spawners and smolts, and model fit ( $\mathrm{R}^{2}$ ). This model shifts the stock-
recruitment curve each year based on whether rearing occurred under Treatment 1 flows (20062007 brood years) or Treatment 2 (2008-2020 brood years). The vertical dashed lines show the offset due to the covariate.

Figure 6.21 Fit of Ricker fall fry-to-fall age-1 parr covariate model using flow treatment period (1or 2) as the covariate for the Coquitlam River during Treatment 1 and 2 years (2006-2020 brood years). The upper-left panel shows the best fit line for the relationship between spawners and smolts, and model fit ( $\mathrm{R}^{2}$ ). This model shifts the stock-recruitment curve each year based the mean April-May discharge. The vertical dashed lines show the offset due to the covariate. 83

Figure 6.22 Fit of Ricker fall fry-to-fall age-1 parr covariate model using the mean discharge during April-May (Mean Spring) as the covariate for the Coquitlam River during Treatment 1 and 2 years (2006-2020 brood years). The upper-left panel shows the best fit line for the relationship between spawners and smolts, and model fit ( $\mathrm{R}^{2}$ ). This model shifts the stockrecruitment curve each year based the mean April-May discharge. The vertical dashed lines show the offset due to the covariate

Figure 6.23 Mean egg-to-fry survival and $95 \%$ confidence intervals for Chum Salmon broods reared under Treatment 1 (2002-2007) and Treatment 2 (2008-2020) in the Coquitlam River study area.

Figure 6.24 Escapement-to-fry stock-recruitment relationships of Chum Salmon during flow Treatment 1 (2002-2008) and Treatment 2 (2009-2019) for the Coquitlam River study area. The best-fit lines intercept the x and y axis at 0 as is typical of stock-recruitment relationships. $\mathrm{R}^{2}$ values reflect the fit of stock-recruitment.

Figure 6.25 Adult-to-ln(fry/adult) stock-recruitment relationships of Chum during flow Treatment 1 (2002-2008) and Treatment 2 (2009-2020) from 7.5 km of the Coquitlam River used for the ANCOVA tests as to whether flow treatment had a significant effect of productivity..... 86

Figure 6.26a Annual escapement and smolt yield in the Coquitlam River study area versus that in the Alouette River during 2002-2014. Values for the Coquitlam are given on the right-hand axis, and values for the Alouette are given on the left-hand axis.

Figure 6.26b Annual escapement, fry and smolt yield in the Coquitlam River versus that in the Cheakamus River during 2002-2017. Values for the Coquitlam are given on the right-hand axis, and values for the Cheakamus are given on the left-hand axis.

Figure 6.27 Estimated abundance of Pink fry outmigrating for the 7.5 km study section of the Coquitlam River. Pink return to south coast rivers on odd years and thus, outmigrate during the spring of even years.

Figure 6.28 Escapement-to-fry stock-recruitment relationships of Pink Salmon during flow Treatment 1 (2002-2008) and Treatment 2 (2009-2019) from 7.5 km of the Coquitlam River. The best-fit lines intercept the x and y axis at 0 as is typical of stock-recruitment relationships. $\mathrm{R}^{2}$ values reflect the fit of stock-recruitment relationship, with the value at the upper end of the

Treatment 2 trend line representing the Treatment 2 fit, and value lower in the figure representing the Treatment 1 fit.92

Figure 6.29 Mean egg-to-fry survival for Pink Salmon in the Coquitlam River during Treatment 1 (2003-2007 brood years) and Treatment 2 (2009 and 2019 brood years). The 2011-2017 brood years with escapement above 10,000 were excluded.

## List of Appendices

Appendix 2.1 Partial surveys, observer efficiency, and survey life ..... 105
Appendix 2.2 Escapement model structure and parameter estimation ..... 107
Appendix 2.3 The number of hatchery Chinook smolts released in the Coquitlam River 2004- 2018 (Scott Ducharme, DFO) ..... 110
Appendix 2.4 Results of the 2006-2018 mark-recapture study to estimate observer efficiencyand survey life for Chum, Pink, Coho and Chinook salmon in the Coquitlam River. Only shadedvalues provide estimates of mean observer efficiency, as they represent cases where theproportion of tagged fish detected was based on a complete survey of the study area within twodays of tagging.112
Appendix 2.5 Unadjusted live counts of Pink salmon. ..... 114
Appendix 2.6 Unadjusted live counts of Chum salmon. ..... 116
Appendix 2.7 Unadjusted live counts of Coho salmon ..... 121
Appendix 2.8 Unadjusted live counts of Chinook salmon during. ..... 126
Appendix 2.9 An example of diagnostic graphs used to evaluate model fit to the observed data(Coho 2008). Top-left graph shows fit of predicted run timing curve (line) to unadjusted countsof spawners over time. Top-right shows relationship of predicted to observed counts with $95 \%$credible intervals for predicted counts. Lower-left graph shows variation in predicted observerefficiency across surveys. Lower-right graph shows the regression relationship betweensurveyor guesstimates of observer efficiency (horizontal axis) and mark-recapture derivedestimates of observer efficiency (vertical axis), with $95 \%$ credible intervals shown for theestimated regression slope.129
Appendix 3.1 Discharge ( $\mathrm{m}^{3} / \mathrm{s}$ ) in Coquitlam River at Port Coquitlam during Steelhead spawning period in 2005 - 2020 (Water Survey of Canada station 08MH002). ..... 130
Appendix 3.2 Survey dates with raw counts of Steelhead redds, estimated new redds, and liveadult counts for all surveys during 2005-2021. Estimated new redds includes the sum of the rawcount and the estimated number of redds that were constructed and then obscured by substratemovement prior to a scheduled survey, based on a redd survey life model.131
Appendix 3.3 Summary statistics for Steelhead escapement to Coquitlam River during 2005-2020 based on redd counts. Minimum and maximum range in escapement reflects uncertainty about the number of redds constructed by each female, and about sex ratio (see Section 3.1.4). ..... 135Appendix 3.4 An example of how raw survey counts were expanded to account for redds thatwere completed and subsequently became undetectable between surveys (see section 3.2.1). . 137
Appendix 4.1 Methods for night snorkeling ..... 138
Appendix 4.2 Mark-recapture experiments to estimate snorkeling detection probability ..... 140
Appendix 4.3 Estimation of fish standing stocks and mean densities ..... 142
Appendix 4.4 Definition of variables of the hierarchical Bayesian model used to estimatejuvenile Coho and Steelhead abundance in the Coquitlam River system. Index sites refer to the12 sites in the Coquitlam River where fish abundance is sampled each year by night snorkeling.Fish size strata (subscript g) apply only to Steelhead (see Section 4.1.5).144
Appendix 4.5 Equations of the hierarchical Bayesian model used to estimate juvenile Steelheadabundance in the Coquitlam River. See Appendix 4.1 for definitions of model parameters,constants, and subscripts. Lower case Arabic letters denote data or indices (if subscripts). CapitalArabic letters denoted derived variables, which are computed as a function of estimatedparameters. Greek letters denote estimated parameters. Parameters with Greek letter subscriptsare hyper-parameters146
Appendix 4.6 Summary of data deficiencies and alternate approaches taken with respect toestimation of parameters and hyper-distributions in the Hierarchical Bayesian Model (HBM)used to estimate juvenile Steelhead and Coho standing stocks in the Coquitlam River during2006-2019.148
Appendix 4.7 Summary of habitat data for night snorkeling and day electrofishing sites in Coquitlam River in 2021 ..... 149
Appendix 4.8 Estimates of juvenile fish density, standing stock, and 95\% confidence intervalsby species and age class in Coquitlam River during 2006-2021. Estimates were derived fromnight snorkeling counts with the exception of 2011 Steelhead ( $0+$ ), which used the electrofishingestimate.150

Appendix 4.9 Mean 3-pass depletion electrofishing density estimates at four one-shoreline sites in the Coquitlam River for 2006-2021. The electrofishing survey was conducted at the same four sites during 2007-2021, whereas in 2006 electrofishing was conducted at 10 shoreline sites located within the annual snorkeling index sites (Decker et al. 2007).152
Appendix 4.10 Summary of 3-pass depletion electrofishing results at four one-shoreline sites inthe Coquitlam River in 2021153

Appendix 5.2 Summary of estimated numbers of Coho, Steelhead and Chum smolts passing the three RST trapping locations (not reach estimates) in the Coquitlam River mainstem in 2020. Mark group indicates the location where fish were initially captured and marked. Also shown are numbers of marked (M), recaptured (R) smolts, unmarked captures (U) and estimated capture efficiencies (R/M). 165

Appendix 5.3 Mark-recapture data used for the BTSPAS estimates for Coho, Steelhead, Chum and Pink at three rotary screw trap sites (RST2, RST3, RST4) in the Coquitlam River mainstem in 2020. Tables include numbers of fish marked in strata $i$, numbers recaptured within the
release strata ( $\mathrm{i}+0$ ) and in subsequent strata $(\mathrm{i}+\mathrm{n})$, and proportion of each strata in which sampling occurred.166

Appendix 5.4 Estimated of the number of Coho and Steelhead smolts outmigrating from reaches 2-4 of the Coquitlam River 1996-2020. Individual estimates for four constructed off-channel habitats and mainstem reaches $2-4$, both individually and combined, which extends 7.5 km downstream from the Coquitlam Dam.

Appendix 5.5 Age-fork length relationships for Steelhead parr and smolts in the Coquitlam River during 2005-2020 derived from scale-aging analysis. 170

Appendix 5.6 Mark-recapture data used to test whether the capture efficiency differed between smolts marked using VIE or fin clips for Coho and Steelhead captures at RST 2 during strata 8 and 9 in 2018. Proportions recaptured are considered unaffected by marking method with p values greater than 0.05 .

Appendix 6.1 Criteria used to consider data sets from other rivers suitable for assessing whether abundance changes between treatment periods on the Coquitlam River occurred elsewhere, which would suggest that flow treatment alone was not the only cause of the abundance change.

Appendix 6.2 References for annual smolt estimates considered for use as controls steams in the BACI analysis for treatment effects for Coho and Steelhead. 171

Appendix 6.3 Mean annual Coho smolt abundance estimates 1998-2018 for the Coquitlam River mainstem and watersheds considered for use as controls for regional changes in freshwater productivity.

Appendix 6.4a Summary of all population estimates for all life stages and species in Coquitlam River, 2000-2021. Values show the abundance of each life stage for the year it was the monitoring occurred. Abundances for the different life stage are also not strictly comparable because study areas differ somewhat for the different components of the monitoring program. 173

Appendix 6.4b Annual survival estimates between several starting and ending life stages for Coho, Chum and Pink Salmon and Steelhead Trout in the Coquitlam River. Egg-to-smolt survival estimates are based on adult escapement upstream of the lowermost smolt trapping site (RST2). Unlike Table 6.4a, year corresponds to the adult return year (brood year), as opposed to the year when the juvenile life stage was present. For survival rates among the juvenile life stages of Steelhead (e.g., fry to age $1+$ parr), year corresponds to the younger life stage. Biased-high survival rate estimates (i.e., >100\%) are shown in red (see Section 6.2).

Appendix 6.5 The Pearson correlation coefficient and the sample size ( N ) for the comparison between Coho smolt abundance in the Coquitlam River mainstem and the streams considered as controls for regional changes in freshwater productivity in the Before-After-Control-Impact (BACI) analysis. The comparison included the years 2000-2009, which represents cohorts
reared entirely or mostly under Treatment 1. We used correlation coefficient value of 0.5 as the minimum value to include a stream in the BACI analysis. 175

Appendix 6.6 Covariates used for Coho adult-to-fall fry Ricker stock-recruitment analysis. All flow metrics based on average 15 minute or hourly discharge for Coquitlam River at Port Coquitlam (Water Survey of Canada, stn. 08MH002). Covariates were transformed to standard deviations with a mean of zero to maintain equal weighting in the model. 176

Appendix 6.7 Covariates used for Coho adult-to-fall fry stock-recruitment analysis. All flow metrics based on average 15 minute or hourly discharge for Coquitlam River at Port Coquitlam (Water Survey of Canada, stn. 08MH002). Covariates were transformed to standard deviations with a mean of zero to maintain equal weighting in the model.177

Appendix 6.8 Annual Steelhead smolt abundance during the Treatment 1 and 2 flow period in the Coquitlam River mainstem and the Alouette River. The Alouette River was used as control for regional changes in freshwater productivity. 178

Appendix 6.9 The Pearson correlation coefficient and the sample size ( N ) for the comparison between Steelhead smolt abundance in the Coquitlam River mainstem and the streams considered as controls for regional changes in freshwater productivity in the Before-After-Control-Impact (BACI) analysis. The comparison included the years 2000-2009, which represents cohorts reared entirely or mostly under pre-Treatment 2 conditions. We used correlation coefficient value of 0.5 as the minimum value to include a stream in the BACI analysis.

Appendix 6.9 Covariates used for Steelhead adult-to-fall fry stock-recruitment analysis. All flow metrics based on average 15 minute or hourly discharge for Coquitlam River at Port Coquitlam (Water Survey of Canada, stn. 08MH002). Covariates were transformed to standard deviations with a mean of zero to maintain equal weighting in the model. 179

Appendix 6.10 Covariates used for Steelhead fall fry-to-fall parr stock-recruitment analysis. All flow metrics based on average 15 minute or hourly discharge for Coquitlam River at Port Coquitlam (Water Survey of Canada, stn. 08MH002). Covariates were transformed to standard deviations with a mean of zero to maintain equal weighting in the model. 179

Appendix 6.11 Preliminary ANCOVA results for Chum 2003-2016 brood years to examine the significance of flow treatment on fry yield during Treatment 1 (2000-2008) and Treatment 2 (2009-2020) in the Coquitlam River including the significance of F values. The null hypothesis in all cases is that the predictive variable is not a significant predictor of fry yield. Escapement x Treatment represents the interaction effect that would produce different slopes of the stockrecruitment relationships for Treatment 1 and 2.

## 1. Introduction

The development of the Coquitlam-Buntzen facilities Water Use Plan (LB1 WUP) was initiated in September 1999 and completed in March 2003. As part of the LB1 WUP, the LB1 WUP Consultative Committee (CC) made recommendations on dam releases in the Coquitlam River based on trade-offs between power, drinking water and fisheries values (BC Hydro 2003). The LB1 WUP was also designed as a long-term adaptive management experiment to compare different flow regimes for the Coquitlam River below the Coquitlam Lake Reservoir. The effect of different flows and other types of enhancements on the productivity of anadromous salmonid populations are often difficult to detect because of the high degree of natural variation in both freshwater and ocean survival (Keeley and Walters 1994; Bradford 1995). Relying on a study by Higgins et al. (2002) that looked at the statistical power to detect changes in fish production in the Coquitlam River under different flow regimes, the CC selected two flow regimes for comparison: the regime of two fish valves fully open ( 2 FV , Treatment 1 ), and the Share the Pain\#6 flow regime (STP\#6, Treatment 2) prescribed by the CC (Table 1.1) that attempts to improve spawning and rearing habitat conditions in the Coquitlam River relative to Treatment 1.

Table 1.1 Scheduled monthly flow releases from Coquitlam Dam under Treatments 1 and 2 of the Coquitlam River Water Use Plan (BC Hydro 2003a).

| Period | Reservoir diversion schedule ( $\mathrm{m}^{3} / \mathrm{s}$ ) |  |  |  |  | Target species and life stage |

| Nov | 12.0 | 10.8 | 1.1 | 4.0 | 1.5 | Chinook spawning |
| Dec | 11.9 | 10.7 | 1.1 | 5.0 | 2.5 | Chinook spawning |

### 1.1 Background

The lower Coquitlam River flows 17 km from the base of the Coquitlam Dam to its confluence with the Fraser River. The stream was first dammed in 1903. The present dam dates back to 1914. As part of LB1 WUP (BC Hydro 2003a), flows in the lower Coquitlam River are regulated through the Coquitlam Dam's low-level outlets, which release flows from the Coquitlam Reservoir. The Coquitlam Reservoir supplies drinking water for the Greater Vancouver Regional District (GVRD) and water for power via a diversion tunnel to Buntzen Lake.

## 1. Introduction

Typical of lotic habitats downstream of dams, spawning and rearing habitat in the lower Coquitlam River (hereafter referred to as the Coquitlam River) has been impacted over the last hundred years by reduced gravel recruitment from upstream sources and increased sedimentation due to reduced peak flows (NHC, 2001). Several gravel pit operations adjacent to Coquitlam River have also affected habitats by contributing large amounts of fine sediment directly to the system. Other impacts are typical of urban streams, and include extensive channelization and dyke construction, road and bridge crossings, alteration of natural drainage patterns and tributary inflows, and the increased discharge of pollutants. Peak, post-dam flows in Coquitlam River can exceed 200 cubic metres per second ( $\mathrm{m}^{3} / \mathrm{s}$, Water Survey of Canada, Station 08MH141). Prior to June 1997, flow releases from the dam ranged from 0.06 to $0.5 \mathrm{~m}^{3} / \mathrm{s}$ (not including occasional spill events). From 1997 to October 2008, minimum flow releases were increased to a range of 0.8 to $1.4 \mathrm{~m}^{3} / \mathrm{s}$, depending on the time of year. This represents the Treatment 1 regime of two fish valves fully open ( 2 FV ), and is the baseline for this adaptive management study.

The Treatment 2 flow regime, Share the Pain\#6 (STP\#6) was initiated on October 22, 2008, with seasonal target flow releases from Coquitlam Dam ranging from 1.1 to $6.1 \mathrm{~m}^{3} / \mathrm{s}$ (Table 1.1). After the knife gate was put into operation, BC Hydro personnel conducted measurements of actual flows during the spring and summer of 2009, and these were compared to modeled flows to verify the theoretical discharge rating curve through the various flow ranges. These measurements indicated that actual flows were consistently higher than predicted ( $2 \mathrm{~m}^{3} / \mathrm{s}$ higher on average than seasonal target releases, Table 1.1). During August and early September, 2009, BC Hydro's Engineering Group worked on updating the flow rating curve for the new gate facility. Once sufficient data was collected, the discharge rating curve was adjusted and brought into service on September 15, 2009. As a consequence, with respect to the flow experiment, 2009 was not strictly representative of Treatment 2. However, given the planned 9 year duration of Treatment 2, this was not considered to have a significant impact on the comparison of the two treatment periods.

The Coquitlam River historically supported all six Pacific salmon, as well as Cutthroat Trout (Oncorhynchus clarki), which are still present in low numbers, and Dolly Varden (Salvelinus malma) char, which appear to have been extirpated. Dam construction also resulted in the extirpation of an anadromous stock of summer Sockeye Salmon (Oncorhynchus nerka), but this species stills exists in the Coquitlam Reservoir in its resident form (Kokanee). Other species inhabiting the Coquitlam River below the dam include Longnose Dace (Rhinichthys cataractae), Prickly Sculpin (Cottus asper), Redside Shiner (Richardsonius balteatus) Pacific Lamprey (Entosphenus tridentatus), and Three-Spine Stickleback (Gasterosteous aculeatus).

### 1.2 Study design

Prior to the implementation of the monitoring program, the CC evaluated several potential flow regimes using flow-habitat models for target species and life histories, with habitat treated as a surrogate for fish productivity (BC Hydro 2003b). Habitat modelling suggested that increased base flows in late summer under Treatment 2 could increase the quantity and quality of juvenile rearing habitat for species with longer freshwater residency periods including Chinook Salmon (Oncorhynchus tshawytscha) and Steelhead Trout (Oncorhynchus mykiss), and that

## 1. Introduction

increased fall and spring base flows could improve spawning success for all anadromous salmonids.

The LB1 WUP was developed as an adaptive management study with the objective of ensuring sufficient information is in place to determine the fisheries benefits of the two test flows and to enable a better understanding of the trade-offs between fisheries, domestic water and power generation. From this a primary management question was developed:

What are the fisheries benefits of flow Treatment 1 (2FV) and Treatment 2 (STP6)?
To answer this, a Before - After (BA) experimental design was developed that included juvenile outmigration as well as adult escapement monitoring with six years of monitoring Treatment 1 flow conditions followed by nine years of monitoring under Treatment 2 conditions. While Steelhead Trout and Chinook Salmon were identified as the key species of interest, lower Chinook abundance necessitated the use of Coho Salmon (Oncorhynchus kisutch), Chum Salmon (Oncorhynchus keta) and Pink Salmon (Oncorhynchus gorbuscha) as surrogates for monitoring.

An expected effect size (increased freshwater productivity) from the Treatment 2 flow regime was not defined in the TOR, however the Fisheries Technical Committee (FTC) predictions ranged from a $0 \%-100 \%$ increase in productivity from Treatment 1 to Treatment 2. Higgins et al. (2002) summarized that this uncertainty in the fish benefits from alternative flow regimes, including STP\#6, were mainly due to: 1) the fundamental uncertainty about the functional relationships between flow-habitat-fish for the Coquitlam River, 2) the poor contrast in available hydrometric data needed to calibrate hydraulic models which necessitated extrapolation of habitat predictions to flow levels above that observed but under consideration by the WUP Consultative Committee, and 3) the unknown influence of spawning substrate quality issues from gravel mining operations and the practical extent to which that impact could be mitigated by implementing deliberate flushing flows from the Coquitlam Dam.

The Terms of Reference (BC Hydro 2006) anticipated this experimental design to have a probability of 0.51-0.59 (power) to detect a $50 \%$ increase in abundance (effect size) and characterizes this level of statistical power as 'moderate'. However, moderate power typically reflects a probability of 0.8 , whereas a probability of 0.5 is more typically considered 'low'. Power levels of 0.51-0.59 reflect the odds of detecting a given change only slightly better than flipping a coin. This review will use 0.8 as the benchmark for acceptable power, which is consistent with the approach used in the power analysis of the Coquitlam WUP Monitoring Program (Higgins et al. 2002).

COQMON-07 focuses on four species: Steelhead Trout, and Coho, Chum, and Pink Salmon. Other fish species in the Coquitlam River are either of too low abundance to effectively monitor, although this appears to be changing for Chinook (see Section 1.2.1), or are not considered to be as high in economic, recreational, or cultural importance. Adult escapement and smolt/fry outmigration are monitored for all four target species. In addition, beginning in 2006, fall juvenile standing stock was assessed for Coho and Steelhead. Coho and Steelhead smolt production is the primary performance measure for the flow experiment. Coho and Steelhead

## 1. Introduction

have lengthy freshwater residencies relative to other target species, and smolt production for these species was judged to be the best indicator of the effects of flow management and dam operation on freshwater production. There is much research (e.g., Bradford and Taylor 1996; Ward and Slaney 1993) suggesting that Coho and Steelhead smolt production is limited primarily by habitat carrying capacity at all but very low levels of adult escapement. If adult returns are insufficient to seed available juvenile habitat, then recruitment effects may confound the relationship between smolt production and habitat. Monitoring escapement in addition to smolt production for Coho and Steelhead allows freshwater production to be evaluated under a scenario of recruitment-limited smolt production by substituting smolts per spawner or egg-tosmolt survival for absolute smolt production, but only if enough years of data are available to reliably define the stock-recruitment relationships. At the least, monitoring escapement provides a means of assessing whether escapement was adequate to seed available habitat based on comparisons with other systems for which reliable stock-recruitment data are available. Monitoring the fall standing stock of juvenile Coho and Steelhead, together with smolt production, is potentially useful in addressing questions about freshwater production bottlenecks in the Coquitlam River. Such as, is overwintering habitat more important than summer rearing habitat in limiting juvenile carrying capacity?

For Chum and Pink, which migrate to saltwater shortly after emergence, habitat conditions in the Coquitlam River determine the quantity and quality of available spawning substrate and incubation conditions for eggs. For these species, fry production and egg-to-fry survival are the most important indicators of freshwater production. Figure 1.1 provides a periodicity chart for different life stages of numerous anadromous salmonids in the Coquitlam River.

Figure 1.1 Life stage periodicity chart for some anadromous salmonids in the Coquitlam River.

Figure 1.2 Map of lower Coquitlam River study area with stream reaches defined by the Coquitlam-Buntzen Water Use Plan Consultative Committee. Note that the majority of reach 4 is directly influenced by releases from the dam.

COQMON-07 focuses on the effects of dam releases on the fish productivity of mainstem habitats in reaches $2 \mathrm{a}, 2 \mathrm{~b}, 3$ and 4, of the Coquitlam River (Figure 1.2). These reaches contain the majority of productive spawning and rearing habitat in the Coquitlam River (Riley et al. 1997; Macnair 2005). The actual boundaries of the study area vary somewhat among components of the monitoring program due to sampling constraints or species distribution (see Sections 1.2.1-1.2.4). Within reaches 2-4, spawning and rearing for Steelhead, Chum and Pink is largely confined to the mainstem (Macnair 2005; Decker et al. 2006). Or Creek is a high gradient, nutrient-poor stream, with limited accessible length, and is the only significant tributary (Figure 1.2). It is confluent with the Coquitlam at the downstream boundary of reach 4. There are several other tributaries, but they are small, with accessible lengths limited to a few hundred metres. In addition to natural habitat, six large off-channel habitats, totalling about $27,000 \mathrm{~m}^{2}$ have been constructed in reaches 2-4 (Decker and Foy 2000). The contribution of tributaries and off-channel sites to the production of Steelhead, Chum and Pink is low, but off-channel sites are used extensively by Coho for spawning and rearing. Constructed off-channel habitat contributed $33 \%-77 \%$ of Coho smolt production in reaches 2-4 (Decker et al. 2009).

The principal objective of this report is to summarize the fish productivity in the Coquitlam River during Treatment 1 and the first 12 years of Treatment 2 by providing population estimates at each monitored life stage for the four target species. This report also provides a thorough description of the study design and sampling methodologies for each component of COQMON07 , an evaluation of potential limitations or problems with the existing study design, and recommended changes to be applied for future years. The remainder of the report is organized in six parts (Sections 2-7). The first four parts (Sections 2-6) address methods and results for the four monitoring components of the COQMON-07: adult salmon escapement surveys, Steelhead redd surveys, juvenile standing stock surveys, and smolt and fry trapping respectively. A discussion of the technical aspects and issues with each monitoring component is included at the end of each of these sections. The rationale for each of the four components and a summary of work completed to date are provided in Sections 1.2.1-1.2.4 below. In the final section of the report (Section 7), fish production across life stages is synthesized for each species for the study period to date. Where possible, we compare productivity data for the Coquitlam River to that in other regulated and non-regulated streams within the region in order to assess the relative productivity of the Coquitlam River in its current state, and to examine whether recent trends in the Coquitlam River have followed those observed in other streams.

### 1.2.1 Adult salmon escapement

Formal surveys of adult salmon escapement were included as a component of COQMON-07 beginning with Chum and Coho salmon in 2002, and Pink salmon during odd years in 2003. Chinook were also enumerated during surveys in all years, but in monitoring years prior to 2007 Chinook escapements were negligible, and were not estimated as part of the monitoring program. During 2007-2014, Chinook escapement increased substantially, largely as a result of hatchery enhancements (M. Coulter-Boisvert, DFO, pers. comm.), and we were able to generate escapement estimates for these years. It should be noted that because adult salmon monitoring was started after smolt monitoring, estimates of egg-to-smolt survival for Treatment 1 were

## 1. Introduction

limited to six, three and five years' of data for Chum, Pink and Coho, respectively (smolt abundance was not estimated for Chinook).

During 2002-2016, and 2018-2020, weekly total counts of live adults by shore-based observers and area-under-the-curve (AUC) methodology was used to estimate adult salmon abundance. The AUC approach requires accurate information about observer efficiency and average spawner survey life (Perrin and Irvine 1990). In 2006 we began conducting markrecapture studies to generate observer efficiency and survey life estimates for Chum and Pink salmon in the Coquitlam River. Salmon escapement estimates appearing in this report differ from previous years' estimates due to the incorporation of new observer efficiency and survey life data based on mark-recapture experiments and the integration of subjective estimates of observer efficiency made by survey crews for individual years, surveys and stream sections. Escapement estimates will continue to evolve in future years as more mark-recapture data is collected and the escapement model is refined. This report describes in detail the results of the 2020 adult salmon escapement results and summarizes population estimates for 2002-2016, and 2018-2020. Due to a transition in the monitoring program, no salmon escapement monitoring was completed during the fall of 2017 .

### 1.2.2 Adult Steelhead escapement

The assessment of adult winter Steelhead escapement, in the form of redd surveys, was included as a component of COQMON-07 starting in 2005. Because Steelhead escapement monitoring was not included as part of the flow experiment until 2005, estimates of egg-to-smolt survival were available only for 2007 onward, which limits egg-to-smolt survival estimates to just one year for Treatment 1, which includes the yield of age- 2 and age- 3 smolts in 2007 and 2008, respectively, from the 2005 escapement year. Prior to 2005, snorkeling crews conducted periodic counts of adult Steelhead in some years (2001-2004) but no attempt was made to relate these counts to actual escapement. With the exception of 1999, when redd counts were conducted in reaches 3 and 4 (see Decker and Lewis 1999), pre-2005 surveys did not include counts of Steelhead redds. Because of the protracted migration and spawning period for winter Steelhead in the Coquitlam River (4-5 months), the high variation in stream residence time among individual fish (Korman et al. 2002), and the highly variable survey conditions within the spawning period, reliable information about residence time and observer efficiency would be needed in order to estimate escapement using counts of adult Steelhead and the area-under-thecurve methodology (Korman et al. 2002). This was considered unfeasible within the scope and budget of the monitoring program given the considerable cost of collecting such information, and the difficulty tagging sufficient numbers of individuals each year from this relatively small population.

Alternatively, in streams that are well suited to the method, redd count surveys can provide a more reliable index of inter-annual trends in escapement than the AUC-type adult surveys. Redd counts can be excellent predictors ( $\mathrm{R}^{2}$ values $>0.9$ ) of Steelhead escapement as estimated by direct trap counts (Freeman and Foley 1985), resistivity counters (Korman and Schick 2015), mark-recapture studies (Jacobs et al. 2002) or the AUC methodology (Gallagher and Gallagher 2005). A pilot study conducted in reaches 3 and 4 in 1999 (Decker and Lewis 1999) indicated

## 1. Introduction

that conditions during the spring Steelhead spawning period in the Coquitlam River were, for the most part, well suited to redd count surveys. Estimating uncertainty ( $95 \%$ confidence bounds) for Steelhead escapement estimates derived from redd counts would require the concurrent use of a second more accurate method (e.g., resistivity counter or mark-recapture program). This is beyond the scope of the current study. Thus, estimates of Steelhead escapement and egg deposition for the Coquitlam River are reported without estimates of precision. Our reliance on literature values for sex ratio and fecundity values could reduce the accuracy of escapement estimates, however, they likely remain reliable as an index of relative change across years.

### 1.2.3 Juvenile Coho and Steelhead standing stock

In 2006 the CC requested that a juvenile standing stock survey component be added to the Coquitlam River Monitoring Program to provide an index of annual abundance for age-0+ Coho and age- $0+$ to age- $2+$ Steelhead. These data, together with adult escapement and smolt abundance estimates, are useful for examining freshwater production bottlenecks at specific juvenile life stages that may relate to specific habitat or flow issues. In September 2006, we conducted a feasibility study to determine the best method for sampling juvenile populations. We compared closed-site three-pass removal electrofishing to open-site night snorkeling counts at 20 m long, one-shoreline sites. We also compared results from shoreline sites and sites that spanned the entire stream channel, using snorkeling counts only. The results suggested that sampling juvenile abundance at full channel sites using night snorkeling counts would be the most effective method for monitoring annual juvenile standing stocks in the Coquitlam River (Decker et al. 2007). Juvenile standing stocks were assessed during 2006 onward using this methodology; mark-recapture experiments were conducted during 2007-2013 to estimate snorkeling detection probability (the percentage of fish present that snorkelers detect), so that snorkeling counts could be expanded to population estimates. This report describes in detail the results of the 2021 juvenile standing stock survey, and summarizes preliminary population estimates for 2006-2021.

### 1.2.4 Smolt outmigrant trapping

Smolt trapping has occurred in the Coquitlam River in various years since 1993 (see Decker and Lewis 2000 for a summary of earlier work). However, earlier studies were intended to compare smolt production at several constructed off-channel habitat sites to that in reach 4 of the Coquitlam River mainstem, as opposed to assessing production in the mainstem as a whole. During 2000-2021, numbers of Coho and Steelhead smolt outmigrants were assessed for a 7.5 km long section of Coquitlam River mainstem that included reaches 3 and 4 and most of reach 2a. Smolt numbers were also assessed for individual mainstem reaches and for the four off-channel sites. Chum and Pink smolt numbers were monitored for the same section of the mainstem beginning in 2003. Smolt numbers in the mainstem were assessed using markrecapture methodology and rotary screw or incline plane traps. Full-span downstream weirs were used at the off-channel sites. This report describes in detail the results of the 2021 smolt trapping program and summarizes population estimates for all species and reaches for 20002021.

## 1. Introduction

## 2 Adult Salmon Escapement

### 2.1 Methods

Returning spawners to the Coquitlam River were enumerated by stream walk surveys conducted on an annual basis during 2002-2016, 2018-2020 for Chum and Coho, and during odd years for Pink. Chinook were also counted during this time period, but prior to 2007 peak live counts were only 21 to 87 fish (J. Macnair, Living Resources Environmental Consultants, data on file), suggesting annual escapements of < 100 to 300 fish. During 2008-2013 counts of Chinook were substantially higher, largely as a result of hatchery enhancement (S. Ducharme, DFO, pers. comm.; Appendix 2.1), and we have included estimates of Chinook escapement 2008 onward in this report. In this report, we have included escapement results for all four species for 2002-2020. No escapement monitoring was completed during the fall of 2017.

Considerable overlap exists for the spawning periods of Pink (early to mid-September - late October), Chinook (mid-September - mid-November), Chum (mid-October - early-December), and Coho (mid-October - mid-January). To address this, we conducted concurrent counts for whichever species were present during a particular survey. Surveys were scheduled to occur weekly throughout the entire spawning period, with the first survey date adjusted to capture the arrival of Pink and/or Chinook, and the last survey date dependent on the end of the spawning period for Coho. However, surveys were often cancelled or postponed due to poor water clarity conditions.

### 2.1.1 Stratified index survey design

For adult salmon, the study area extends downstream from Coquitlam Dam to the downstream boundary of Reach 1 at the Maple Creek confluence, encompassing reaches 1-4 in their entirety (Figure 1.2). Reach 0 (Fraser River confluence to Maple Creek) was excluded as it contains little spawning habitat and because fish entering the Hoy/Scott Creek system often hold in this reach and could be confused with fish destined for upper reaches in the Coquitlam River. Due to the length of the study area (approximately 12.8 km ), and the concentration of spawning activity within specific sections, sampling efficiency was improved by stratifying the survey to focus on five key areas hereafter referred to as index sites A-E (Figures 2.1, 2.2). Irvine et al. (1992) demonstrated that using a stratified index design to select areas to conduct visual surveys for adult Coho provided accurate estimates of escapement at a lower cost than more intensive methods such as mark-recapture or operation of counting fences. Coquitlam River index sites were originally developed from spawning distribution maps developed as part of the LB1 WUP. The boundaries of these sites were refined during the first several years of the study under Treatment 1, and were further refined over the first several years of the study under Treatment 2. The five index sites have a collective length of approximately 9 km , or $63 \%$ of the total length of the survey area, but account for a higher percentage of the total fish present during any one survey because they encompass the majority of available spawning habitat. All potential holding and spawning habitats were surveyed within each index site, including mainstem areas, natural side-channels and braids, and constructed off-channel habitat.

Figure 2.1 Map showing adult spawning index sites A-C in the lower portion of Coquitlam River study area (reaches 1, 2a)

Figure 2.2 Map showing adult spawning index sites D and E , in the upper portion of Coquitlam River study area (reaches 2b, 3 and 4).

To account for spawners present in the study area, but not in one of the five index sites, on several occasions each year, the survey was extended to include the entire 12.8 km length of the study area. We attempted to complete three full surveys of the study area during the spawning period for each species, with some dates providing full surveys for more than one species. To address possible temporal variation in the proportion of spawners in non-index sites, surveys were scheduled in an attempt to capture early, peak, and late portions of the spawning period for each species. There were occasions each year when it was not possible to survey all five index sites due to poor water visibility. We used data from complete surveys of the study area to 'fillin' counts for non-surveyed index sites and non-index sites on occasions when not all of the study area was surveyed (see Section 2.1.2).

Spawner surveys were performed by a crew of two people, equipped with chest waders and polarized glasses, who traveled in an upstream direction, with one person on either side of the river. The survey team has been very consistent over the project life ( $1^{\text {st }}$ Crew member: Jason McNair, 2002-2020; $2^{\text {nd }}$ crew member: Gord Lewis 2002-2006; Kris Kehler 2007, 2015-2016; Thibault Doix 2008-2015). This relative consistency likely reduced between-observer variance. The survey crew minimized the likelihood of making duplicate counts by regularly discussing which portions of the river channel each person was responsible for. Surveyors carried walking staffs that they used to probe under cutbanks and LWD accumulations in order to detect fish that were not in plain view. Total numbers of live and dead adults were recorded during each survey, but only data for live fish were used to estimate escapement. In most cases, stratified counts of the five index sites were completed in one day, while surveys of the entire study area were completed over two days.

With the onset of Treatment 2 in October 2008, dam releases during the spawning period increased, particularly during the latter part when the majority of Coho spawning occurred. In 2009, the survey crew concluded that, shore-based observations were less effective for Coho under the new flow regime because of increased water depths and turbulence in many areas where these fish were found. During the latter part of the survey period in 2009 (DecemberJanuary), the survey crew opted to modify the survey design by incorporating one crewperson equipped with a dry suit and snorkeling gear, in addition to 1-2 shore-based observers. Comparisons of counts made by snorkelers and shore-based observers suggested that snorkelers detected 4 - to 6 -fold higher numbers of Coho than shore-based observers under Treatment 2. The effect of this shift in protocol with regard to estimating Coho escapements is discussed in Section 2.2.2. Field crew did not report an obvious difference in the detectability of other salmon species between Treatments 1 and 2, and there was some support for this based on similar mark-recapture derived estimates of observer efficiency for Chum salmon under the two treatments (see Section 2.2.2).

### 2.1.2 Partial surveys, observer efficiency, and survey life

See Appendix 2.1

### 2.1.3 Escapement model structure and parameter estimation

See Appendix 2.2
2. Adult Salmon Escapement

### 2.2 Results and Discussion

### 2.2.1 Survey conditions and run timing

Unadjusted survey counts from all surveys during 2002-2016 and 2018-2020 are shown for Chum, Coho, Pink and Chinook in Appendices 2.5-2.8. The typical period of peak spawning was the last week of October for Chum, the second week of December for Coho, and the last half of October for Chinook. The reliability of estimates depends on surveys encompassing the entire migration but particularly peak conditions, as was the case for all four species in 2020 (Figure 2.3). For modeling purposes, the maximum length of the spawning period for Chum, Pink, Coho, and Chinook was 119 (September 3-December 30), 82 (September 1-November 21), 130 (September 20-January 27), and 99 (September 3-December 10), days respectively.

Figure 2.3 Spawning run timing base on survey counts for Chinook, Chum, Coho and Pink Salmon in the Coquitlam River during 2020 (red line) and 2002-2019 (grey).

Survey conditions during the 2020 were moderate to poor. Water column visibility ranged from 0.5 m to more than 1.5 m across the surveys with generally lower visibility as the survey season progressed (Table 2.1). This corresponded to a general trend of decreasing observer efficiency 'guestimates' as the season progressed (Table 2.1). Even with a high frequency of storm events in the 2020 survey season, all but four surveys occurred at or near base flows and with a discharge of less than $15 \mathrm{~m}^{3} / \mathrm{s}$ (Figure 2.4). This increased the likelihood that survey conditions are sufficient in all index sites, which improves the reliability of survey counts.

## 2. Adult Salmon Escapement

Table 2.1 Water column visibility (m) at permanent measurement points at index sites A-E and surveyor 'guesstimates' of observer efficiency for Chum salmon (see Section 2.1.2) during surveys of the Coquitlam River for the 2020 brood year.

## 2. Adult Salmon Escapement

Figure 2.4 Daily flows in Coquitlam River at Port Coquitlam during the fall and winter spawning period in 20202021 (Water Survey of Canada, stn. 08MH141). Survey days are represented by red dots.

### 2.2.2 Observer efficiency and survey life

### 2.2.2.1 Observer efficiency

Since 2006, 24 estimates of observer efficiency were obtained for all species combined. No observer efficiency estimate was obtained during 2020. Observer efficiency for Chum averaged $48 \%$ across 10 mark-recapture experiments (range: $33 \%-69 \%$; Table 2.2); with similar means for Treatment 1 and Treatment 2 ( $50 \%$ and 48\%, respectively; Appendix 2.2). For Pink, seven mark-recapture experiments yielded an average observer efficiency estimate of $66 \%$ (range: 49\%-85\%; Table 2.2, Appendix 2.4). For Coho, three mark-recapture experiments under Treatment 2 provided average observer efficiency estimates of $70 \%$. The value for Coho is relatively high compared to observer efficiency estimates reported for Coho in other streams (Irvine et al. 1992). The addition of an underwater observer to the survey crew, beginning in 2009 (see Section 2.1.1), was presumably a contributing factor. In the absence of an underwater observer, observer efficiency during Treatment 1 for Coho in the Coquitlam River was likely lower than the Treatment 2 average of $70 \%$; and was likely lower than the mean value of $47 \%$ for Chum, which spawn earlier in the season, and are less associated with cover and deep pools. For Chinook, two mark-recapture experiments under Treatment 2 provided average observer efficiency estimates of $60 \%$. Due to the small sample size, we combined Coho and Chinook observer efficiency estimates for generating Coho population estimates. Also, given the absence or near absence of data, the observer efficiency during Treatment 1 can only be approximated for Coho, Chinook and Pink (see Section 2.2.2.3).

Table 2.2 Averages and absolute ranges for observer efficiency estimates (proportion of live salmon present that are visually detected) derived from mark-recapture experiments, and subjective 'guesstimates' of observer efficiency made by the survey crew for the same surveys during which the mark-recapture experiments occurred (see Section 2.1.2).

|  | Chum | Pink | Coho | Chinook | All species |

| Number of estimates | 6 | 5 | 3 | 2 | 16 |
| mean of estimates | 8.4 | 10.7 | 16.4 | 7.7 |  |
| range of estimates | $6.5-9.9$ | $6.8-15.5$ | $11.6-15.2$ | $7.7-8.5$ |  |
| maximum survey life for individual fish | 16 | 20 | 28 | 25 |  |

Mark-recapture experiments completed to date have been limited to the early or middle (peak) portions of the spawning period for each species, with no tagging events occurring after November 1 for any species except Coho. For Chum and Coho, which spawn later in the fall when poor survey conditions occur more frequently, observer efficiency estimates likely represent the upper range, rather than average values for the Coquitlam River. This is because the same poor river conditions that lead to low observer efficiency also make it difficult to capture fish for the mark-recapture experiments. Without this information, we were unable to confirm observer efficiency through the full range of survey conditions. We consider this source of uncertainty one of the primary reasons the HBM is unable to estimate the precision of escapement estimates. It is important that future efforts be made to conduct mark-recapture experiments as late in the season as possible, and during periods of higher flows and lower visibility, so that the actual range in observer efficiencies can be better represented in the escapement model.

The issue of poor spatial distributions of marked populations of Chum, Pink and Chinook has improved since 2007 when marking occurred in only one location which provided little information about observer efficiency in the remainder of the survey area. Since 2006, 13 of 23 mark-recapture experiments included marking at two different sections of the Coquitlam River. This provided more spatially representative estimates of observer efficiency, but rendered the data less reliable for assessing survey life because fish captured in the upper river were less likely to be new arrivals to the study area (see below). See Decker et al. 2010 for the rational for distributing marking sites throughout the entire survey area.

## 2. Adult Salmon Escapement

In some cases, marked populations of Chum, Pink and Chinook were skewed to males, and were likely unrepresentative of the sex ratios of the population as a whole (Appendix 2.2). Bias in the sex ratio of marked populations can result in a bias in observer efficiency and survey life, if these parameters differ for male and female spawners (Perrin and Irvine 1990).

### 2.2.2.2 Survey life

Mark-recapture data for 2006-2019 provided limited information about survey life (number of days fish are in the survey area) for each species. Obtaining estimates of survey life requires conducting multiple consecutive surveys (minimum of three) of the entire study area every few days following a tagging event, and this was frequently impossible due to unsuitable survey conditions. A total of 16 estimates of survey life were obtained, seven for Chum, three for Coho, six for Pink and two for Chinook (Table 2.2). Based on the area-under-the-tag-depletion curve method (Perrin and Irvine 1990), mean survey life values ranged from 7.5 days for Chum, to 16.4 days for Coho and decrease as the date they enter the study area increases (Figure 2.5). Based on estimates from the Coquitlam River, the maximum survey life (maximum number of days between when a fish was tagged and subsequently detected) ranged from 16 days for Chum to 28 days for Coho (Table 2.2). Survey life estimates for salmon in the Coquitlam River were less than mean values reported for the same species in other streams, but were still within the reported range (see next section), suggesting that survey life is relatively short in the Coquitlam River. However, survey life estimates for the Coquitlam River are biased low to some degree because salmon were present in the study area for an unknown period of time prior to being captured (as opposed to being captured while migrating past a weir). This bias was further exacerbated by the fact that during many of the mark-recapture experiments, fish were captured and tagged in the spawning areas at the upstream index sites in order to better distribute tags for the purpose of estimating observer efficiency (see above). Additionally, in order to compute estimates of survey life it was necessary to assume that observer efficiency remained constant across a series of surveys following a tagging event. Yet, in several of the mark-recapture experiments, the number of tagged fish detected actually increased from one survey to the next, indicating that observer efficiency had increased over time, rather than remaining constant. While it is apparent this assumption isn't satisfied when observer efficiency increases substantially, survey life bias would also occur with a drop in observer efficiency, but would go undetected due to the inability to distinguish between the effects of observer efficiency and survey life under these conditions.

Figure 2.5 Modeled relationship between mean survey life and day of arrival in the study area for Chum, Pink, Coho, and Chinook salmon in the Coquitlam River based on empirical data from other streams.

Similar to observer efficiency, survey life experiments were skewed towards the early- to mid-spawning period. For Pacific salmon, survey life tends to be greater for early-run fish compared with those spawning later in the season (Perrin and Irvine, 1990). Without more survey life experiments later in the spawning season, we weren't able to confirm the magnitude of difference between early and late run fish.

With a biased estimate of survey life, escapement estimates can still provide a reliable index of adult abundance as long as the actual survey life was relatively consistent across years. An inaccurate estimate of survey life will bias escapement estimates to a similar degree, yet the relative change between years could still be accurate.

Figure 2.6 Relationship between the surveyor's 'guesstimate' of observer efficiency and observer efficiency estimated from mark recapture experiments for Chum, Pink and all species combined conducted opportunistically since 2006 in the Coquitlam River.

### 2.2.2.3 Modeling observer efficiency and survey life

For Chum, subjective guesstimates of observer efficiency made by the survey crew for surveys where mark-recapture estimates of observer efficiency were available ranged from 55\%$100 \%$, and averaged $76 \%$ (Table 2.2). When compared to mark-recapture estimates of observer efficiency, the surveyor guesstimates were biased high, but were moderately useful predictors of observer efficiency for Chum (linear regression, $\mathrm{n}=10 ; \mathrm{R}^{2}=0.38$; Figure 2.6). For Pinks, surveyor guesstimates ranged from $55 \%$ to $100 \%$ for five surveys for which mark-recapture data were available (Table 2.2). Surveyor guesstimates explained less than one quarter of the variation in mark-recapture derived estimates of observer efficiency among surveys for Pinks ( $n=7 ; \mathrm{R}^{2}=0.23$; Figure 2.6). However, this relationship is highly uncertain, being based on only seven observations. For Chum and Pink, we used the regression relationships in the escapement model to estimate observer efficiency for individual surveys based on the guesstimates of observer efficiency, and to model error in estimated observer efficiency (see equations 2.8 and 2.9). For Coho, surveyor guesstimates over the three surveys ranged from $67 \%$ to $73 \%$, which is a poor reflection of common survey conditions (range for all years, 0.45-1.0). Unfortunately, the guesstimates were negatively related to the mark-recapture data (linear regression, $n=3 ; \mathrm{R}^{2}=0.49$; Figure 2.6), which increases uncertainty in the population estimation model. For Chinook, there were only two mark-recapture estimates of observer efficiency available (Table 2.2), which provides no useful information about the relationship between surveyor guesstimates and actual observer efficiency, or even what the average observer efficiency in the Coquitlam River might be. In light of the poor relationship for Coho and limited information for Chinook, in order to model observer efficiency, we regressed surveyor guesstimates against mark-recapture derived estimates of observer efficiency using pooled data for all four species ( $n=22 ; R^{2}=0.17$; Figure

## 2. Adult Salmon Escapement

2.6). Mean observer efficiency (based on mark-recapture) across all species was $60 \%$ compared to observed means of $76 \%$ and $60 \%$ for Coho and Chinook, respectively (Table 2.2).
Furthermore, existing information is too sparse and variable to evaluate whether an assumption for pooling (similar relationship between mark-recapture observer efficiency and guestimates for pooled species) is satisfied.

Given the limited and uncertain survey life data for all four salmon species in the Coquitlam River, we relied on reported values from other studies to inform the parameterization of survey life in the escapement model. Perrin and Irvine (1990) summarized studies of survey life for Pacific salmon. They reported that for Chum, average survey life was 12 days (range= $4-21$ days, $n=54$ ), and varied little between early and late portions of the spawning period (14 and 11 days, respectively). Average survey life for Pink was 17 days overall, and 24 and 15 days respectively, for the early and late portions of the spawning period (range $=5-41$ days, $n=36$ ). Average survey life for Coho was 11 days (range $=3-15$ days, $n=22$ ), with no information available about differences between early and late portions of the spawning period. Average survey life for Chinook was 12 days (range $=3-20$ days, $n=38$ ). We adjusted the $\lambda_{\mathrm{c}}$ and $\lambda_{\mathrm{s}}$ parameter values for each species to provide early, mean, and late period survey life values for Chum (12, 10, and 9 days, respectively); Pink ( 18,13 , and 9 days); Coho ( 18,12 , and 8 days); and Chinook (15, 12, and 11 days) (Figure 2.3). To model error in survey life, the coefficient of variation for survey life ( $\lambda_{\mathrm{v}}$ ) was set at 0.65 for each species, based on an intensive study of survey life of Pink salmon by Su et al. 2001.

### 2.2.3 Escapement model

The "no overdispersion" version of the escapement model provided good fits of predicted numbers of fish present (i.e., predicted run timing survey) to observed weekly counts of Chum, Pink, Coho and Chinook, allowing for plausible estimates of escapement and run timing. However, because true error in the count data exceeded that assumed by a regular Poisson distribution (as opposed to an overdispersed Poisson distribution; see Section 2.1.3.2), 95\% credible intervals for escapement estimates were unrealistically low, and were therefore not reported.

### 2.2.4 Escapement estimates

Estimates of escapement for all species in all years are summarized in Table 2.3. Among years, estimated escapements ranged from 7,000-78,000 for Chum; 900-14,000 for Coho; 1,20034,000 for Pink; and 123-8,000 for Chinook. It is important to note that escapement is an insensitive measure for comparing fisheries benefits of Treatment 1 and 2 flows owing to the large role of ocean survival (particularly its' variability) on the number of adult returns. Trends reported here are products of freshwater and marine conditions. For all species, escapement has been much higher during Treatment 2 than during Treatment 1 (Table 2.4). Mean escapement has increased four-fold for Pink and Chinook, three-fold for Coho and two-fold for Chum compared with Treatment 1. While the mean escapement for Pink and Chum have been higher during Treatment 2, the escapement estimates for 2019 were the lowest and second lowest, respectively, since surveys began in 2002 (Table 2.4). Escapement estimates for Coho and

Chinook during Treatment 1 years should be treated as approximations and are likely not comparable with Treatment 2 (See section 2.2.2.1).

Table 2.3 Annual escapement estimates for Chum, Pink, Coho and Chinook salmon for the years 2002-2016 and 2018-2020. Also included are the mean abundance estimates during Treatment 1 (2002-2008) and Treatment 2 (2009-2020).

| Year | Treatment | Chum | Pink | Coho | Chinook |
| :---: | :---: | :---: | :---: | :---: | :---: |

| Treatment 1 Mean |  | 23,911 | 4,214 | 1,761 | 656 |
| Treatment 2 Mean |  | 31,724 | 13,189 | 9,212 | 1,946 |

### 2.2.6 Adult habitat distribution and access to off-channel sites

Chum salmon in particular show a preference for mainstem spawning habitat in the Coquitlam River (Table 2.4). This preference has been noted in many studies for Chum salmon in medium-sized rivers (Salo, 1991). For Chum, there was a reduction of approximately $10 \%$ in the proportion of Chum spawning in mainstem habitats following the initiation of the Treatment 2 flow regime in 2008 (Treatment : $82 \%-90 \%$, Treatment 2: 69\%-81\%; Table 2.4). It is unclear whether this was an artifact of reduced observer efficiency in the mainstem when flows had increased after October 22; whether it was due to the increased availability of off-channel habitats; or a combination of both. Higher mainstem flows under Treatment 2 gave salmon easier access to off-channel habitats, and increased the amount of available spawning habitat in some constructed off-channel sites, mainstem areas and natural side-channels. In addition, adult Chum show a preference for spawning in the lower reaches of the Coquitlam River, (an average of $63 \%$ of adult Chum spawning in index sites A-C during 2002-2020; Table 2.5). Chum salmon have a brief freshwater residency and often spawn exclusively in the lower reaches of river

## 2. Adult Salmon Escapement

systems (Salo 1991). Spawning gravels are also more abundant in the lower reaches of the Coquitlam River.

During Treatment 1 and 2, Pinks made greater use of mainstem sites for spawning than offchannel habitats (Treatment 1:55\%-71\%, Treatment: 259-76\%; Table 2.4). Pink Salmon also have a brief freshwater residency period, but unlike Chum, Pink spawners make greater use of spawning areas in upper reaches of the Coquitlam River. Depending on the year, the proportion of Pink spawning in the two uppermost sites ( $D$ and $E$ ) ranged from $44 \%-72 \%$ (Table 2.5).

Table 2.4 Adult spawning distribution by habitat type during Treatment 1 and 2, and the 2008 transition year. Treatment 2 flows were initiated October 22, 2008. Proportions shown are calculated based on counts of actively spawning fish only, during surveys when all five index sites were completed. $\mathrm{M} / \mathrm{S}=$ mainstem, $\mathrm{NOC}=$ natural offchannel, $\mathrm{OCR}=$ off-channel restoration site, and $\mathrm{OC}=$ off-channel sites combined.

The trend for Coho of low off-channel habitat (natural or enhanced) use during Treatment 2 continued in 2020 with usage of $23 \%$ (Table 2.4). The combined natural and enhanced offchannel habitat use dropped from 19\%-73\% during 2002-2007 to 6\%-16\% during 2009-2020 (Table 2.4). This shift commenced prior to Treatment 2 and coincided with the modifications to the Coquitlam Dam and dewatering of the Grant's Tomb off-channel site in 2005, which accounted for the majority of off-channel use. The change in relative use between mainstem and off-channel habitat may reflect the higher carrying capacity of the mainstem as well as changes in off-channel habitat capacity. In terms of the number of Coho, the maximum off-channel use has remained relevantly consistent across treatment periods but varied considerably across years (Figure 2.7). With the several fold higher escapement levels from 2010 onward, use increased disproportionately in the mainstem habitat. Coho salmon showed a preference for the upper

## 2. Adult Salmon Escapement

reaches of the Coquitlam River (sites D and E accounted for 59\%-99\% of Coho spawning during 2002-2020; Table 2.5).

Evidence of movement barriers for spawning adults was not apparent at any time during Treatment 1. Fish arriving during the late summer low flow period (which in 2006 lasted until the middle of October), were observed at all index sites. However, observations by the survey crew suggest that low flows did impede access to natural and enhanced off-channel sites in some instances. For example, during a low flow period in 2005, Pink did not enter off-channel sites until October 2, and in 2006, Chum avoided off-channel sites until October 13. Delayed migration into off-channel areas was not apparent during 2008 when flows were increased under Treatment 2. Under Treatment 2, all index sites continue to be accessible to spawning adults throughout the entire escapement period.

Table 2.5 Estimated average proportion of Chum, Pink, Coho and Chinook salmon spawning populations present at each index site (A-E) and at non-index (NI) sites during 2002-2016 and 2018-2020.

## 2. Adult Salmon Escapement

Figure 2.7 Estimated numbers of Coho spawning in mainstem and side-channel habitat in the Coquitlam River 20032020. Note that habitat type was not recorded during the 2002 surveys.

### 2.3 Implication for hypothesis testing

Adult escapement monitoring is providing sufficient information to evaluate the fisheries benefits of Treatment 1 and 2 for Coho but not for Pink or Chum. For Coho, the evaluation of flow treatments depends primarily on smolt production estimates, given that the stockrecruitment relationship to date suggest smolt production is limited by rearing habitat. In this situation escapement estimates only serve the purpose of confirming that escapement was sufficient to reach the juvenile carrying capacity (see Figure 6.1). Beyond this minimum value ( $\sim 800$ fish), smolt production appears insensitive to escapement. Furthermore, we do not recommend using Coho escapement for any between-treatment comparisons since survey methods differed between Treatment 1 and 2, and all Coho mark-recapture experiments occurred during Treatment 2. Given the switch to replacing one of the foot-surveyors with a snorkeler during Treatment 2, it is likely observer efficiency was higher than during Treatment 1. Using the same observer efficiency for Treatment 1 and 2 could lead to underestimates for Treatment 1.

For Chum and Pink, our inability to calculate the precision for escapement estimates reduces the reliability of inferences drawn from this data. Unlike for Coho, the Chum and Pink stockrecruitment relationships to date point to escapement-limited fry production (Figure 6.6), which depends on both juvenile and adult estimates to detect treatment effects. This type of regression based analysis assumes that the adult abundance (x axis) is without error, or at least of much less error than juvenile abundance (Zar 1999). The Coquitlam River data is far from satisfying this assumption. While stock-recruitment analyses rarely satisfy this assumption, knowing the precision of our estimates would allow us to exclude very imprecise estimates, which may increase our ability to detect differences between treatments. Using mean counts as an index of escapement can corroborate HBM results when surveys include peak counts but are still subject to error with sparse data. As mentioned in Section 2.2.3, we think that our inability to calculate credible, precise estimates stems from the lack of Coquitlam-specific survey life information and/or insufficient mark-recapture data.

## 3 Adult Steelhead Escapement

### 3.1 Methods

During 2005-2021, we conducted periodic redd surveys to assess the cumulative number of redds constructed during the spawning period. To convert redd counts to indices of adult winter Steelhead abundance and potential egg deposition, we used empirical data from studies of winter Steelhead in other coastal streams to approximate the number of redds constructed by each female, the average sex ratio, and mean fecundity per female (see section 3.1.4). The variation in redd counts among observers was not investigated, but was minimized by having the same crew conduct all surveys. Steelhead redds become increasingly difficult to detect over time as their characteristic features become obscured by algal growth and substrate movement during high flows. In a small number of years it was necessary to use redd survey life data (i.e., the period of time following initial construction during which a redd can be positively identified) to adjust redd counts upwards to account for redds that we failed to detect due to survey intervals exceeding redd survey life (see Section 3.1.3).

### 3.1.1 Description of study area and survey methods

For Steelhead redds, the study area extended approximately 10.8 km from the Coquitlam Dam downstream to the Patricia Footbridge, and included reaches 2a, 2b, 3, and 4 (Figures 3.1, 3.2). Reach 1 was omitted as minimal Steelhead spawning occurs there. During 2005-2006, it was found that the majority of Steelhead spawning occurred during a seven-week period (midMarch - early May). The analysis of previous years' data indicated that all redds remained visible with a seven day survey interval and that only a very small proportion went undetected with a 14 day survey interval (see Section 3.1.3). As such, our target survey frequency was every two weeks for the entire spawning period. We attempted to conduct surveys just prior to high flow events in order to minimize the number of new redds becoming obscured by substrate movement before they could be detected. Owing to the length of the study area, each survey was completed over a two-day period.

Redd surveys were conducted by two trained technicians who were familiar with Steelhead spawning locations in the Coquitlam River and had considerable experience identifying Steelhead redds. During each survey, one crewmember wore a dry suit and snorkeling gear and searched for redds in deep water, while the other wore chest waders and searched for redds in shallower water along the banks. The shoreline observer marked the location of each redd detected by either crew member with numbered flags and a global positioning system (GPS) to prevent double counting on future surveys, and to provide estimates of redd survey life (see section 3.1.3). Additional data collected for each redd included width and length, specific location within the stream channel, and average substrate size. The crew also recorded the number of live adults observed on each survey, along with their location, and, if possible, their approximate fork length, sex, and the absence of an adipose fin (indicating hatchery origin). The observation data of live adults collected during redd counts was not used to estimate escapement.

Figure 3.1 Steelhead redd locations in reaches 2b-4 in Coquitlam River in 2006, which was the highest escapement year during 2005-2021. Coquitlam Dam is the upstream boundary of the survey area. See Figure 3.2 for redd symbol legend.

Figure 3.2 Steelhead redd locations in reaches 2a-2b in Coquitlam River in 2006. The downstream boundary of reach 2 a is also the survey area boundary.

## 3. Adult Steelhead Escapement

### 3.1.2 Redd Identification

Redds were identified as approximately dish-shaped excavations in the bed material, often of brighter appearance than surrounding substrates, accompanied by a deposit beginning in the excavated pit and spilling out of it in a downstream direction. Disturbances in the bed material caused by fish were discriminated from natural scour by:
i) the presence of tail stroke marks;
ii) an over-steepened (as opposed to smooth) pit wall often accompanied by perched substrate that could be easily dislodged down into the pit, and often demarcated by sand deposited in the velocity break caused by the front wall;
iii) excavation marks alongside the front portion of the deposit demarcating the pit associated with earlier egg laying events, and
iv) a highly characteristic overall shape that included a 'backstop' of gravel deposited onto the unexcavated substrates, a deposit made up of gravels continuous with this backstop and continuing upstream into the pit, and a pit typically broader than the deposit and of a circular shape resulting from the sweeping of gravels from all sides to cover the eggs (in a portion of redds gravels are swept into the pit from only one side, often a shallow gravel bar on the shore side).

A second important determination was whether fish had actually spawned at a location where an excavation had been started. 'Test digs' were considered to be pits, often small, accompanied by substrate mounded up on the unexcavated bed material downstream but with no accompanying gravel mound downstream of the pit, which would denote at least one egg deposition event. In the case of a test dig determination, the mound of gravels would typically be short and narrow around the downstream side of a relatively small pit. Potential test digs were tagged and re-examined on subsequent surveys to determine if they had been further developed into actual redds.

Redds constructed by resident cutthroat or rainbow trout, or lamprey were distinguished from Steelhead redds by their considerably smaller size, lack of a large deposit downstream of the pit, and a conical, or bowl shape, rather than a rectangular shape.

In areas of limited gravel or high redd abundance, or where spawning site selection is highly specific, superimposition of redds can occur (Baxter and McPhail 1996). Owing to the relatively high survey frequency (see below), undercounting of Steelhead redds as a result of redd superimposition is not likely to be a substantial source of negative bias in estimates of Steelhead spawner abundance in the Coquitlam River. Redds are usually detected and their locations recorded before new redds are superimposed. In cases where we do encounter superimposed redds, we count redds based on a subjective evaluation, with the most recent complete redd(s) counted and the disturbed remains of prior redds being estimated in relation to it. A greatly extended deposit length (subjectively evaluated to be at least twice the length of a 'typical' deposit length) constitutes grounds to consider whether a second female had made use of the pit created by a first to construct a separate redd.

## 3. Adult Steelhead Escapement

### 3.1.3 Redd survey life

In most cases, Steelhead redds can be readily detected upon initial construction, but over time, they become undetectable as they are obscured by scour or deposition, regrowth of periphyton, or superimposition of new redds. Thus, survey frequency is an important consideration in designing redd surveys, particularly for streams like the Coquitlam River, where moderately high flow events can occur during the Steelhead spawning period. If the length of time between surveys exceeds average redd survey life, then undercounting will occur. Freymond and Foley (1985) reported winter Steelhead redds remaining easily identifiable for a period of 14 to 30 days in coastal Washington State streams. Based on five years' of data from several coastal Oregon State streams, Jacobs et al. (2002) concluded that, on average, $95 \%$ of winter Steelhead redds remain visible one week after completion, while $86 \%$ remain visible after two weeks.

Across all years, our target of bi-weekly surveys, had we met them, would likely have resulted in negligible undercounting of redds due to survey intervals exceeding average redd survey life. In 2021, with intervals of 15 days or less, we estimated the number of redds simply as the sum of new redds ( $x_{i}$ ) counted during $n$ surveys (Equation 3.1). Only if the case where the interval exceeds 15 days did we use the redd life model to estimate the number of missed redds. See Decker et al. 2010 for a description of methods used to estimate redd survey life and how this is used to estimate the number of redds not visible when survey intervals exceed 2 weeks. Numbered flags were used to identify new redds (or groups of redds) during each survey. The visibility of previously flagged redds was evaluated during each survey to further refine the redd survey life model.

$$
\begin{equation*}
N=\left(\sum_{i=1}^{n} x_{i}\right) \tag{3.1}
\end{equation*}
$$

### 3.1.4 Female escapement and egg deposition

The objective of the Steelhead redd survey component is to enable smolt production to be related to spawning effort. Redd numbers are a direct measure of spawning effort and egg deposition. So, for the purposes of this study, we considered that estimating the total number of redds is as useful as estimating the total adult escapement. However, the number of recruits per spawner is commonly expressed as the number of smolts per female. Following this convention, we converted our estimates of total redd abundance to total female abundance by relying on empirical estimates of the average number of redds per female for winter Steelhead in Pacific coastal streams. Gallagher and Gallagher (2005) reported redds/female values for winter Steelhead in several streams, but their estimates were based on mark-recapture and AUC estimates that were themselves highly imprecise. Freeman and Foley (1985) reported the average number of redds per adult in Snow Creek, Washington State, but not the average number per female. The most robust estimate we were able to obtain was from a study of winter Steelhead in Oregon State coastal streams by Jacobs et al. (2002) that compared total redd counts to accurate estimates of female escapement for four streams over three years using total counts at full-span upstream fences, or at upstream fences coupled with intensive mark-recapture methodology. The number of redds per female derived by Jacobs et al. (2002) ranged from 0.75

## 3. Adult Steelhead Escapement

to 1.63 and averaged 1.2 , with relatively little variability among years for individual streams. We used this value ( 1.2 redds/female) to convert total redd numbers to female escapement.

The total number of adult female Steelhead in the surveyed portion of Coquitlam River ( N ) was approximated as:
$N=\left(\sum_{i=1}^{n} x_{i}\right) \div 1.2$
Where $\mathrm{x}_{\mathrm{i}}$ is the cumulative number of new redds summed across n surveys and 1.2 is a constant representing the number of redds per individual female spawner. In the absence of fecundity data for Coquitlam River Steelhead, we substituted average fecundity for winter Steelhead (3,700 eggs/female) in the Keogh River on northern Vancouver Island (Ward and Slaney 1993). We assumed $50 \%$ of adult Steelhead in the Coquitlam River were female, which is commonly reported for Pacific coastal winter Steelhead (Jacobs et al. 2002). To reflect the uncertainty in the Steelhead escapement estimates arising from uncertainty about the average number of redds per female and sex ratio, the possible minimum and maximum range in escapement in any given year was approximated by arbitrarily varying redds/female by 1.0-2.0, and the proportion of females in the population using sex ratios from five other winter Steelhead streams (0.42-0.63; Jacobs et al. 2000, 2002).

### 3.2 Results and Discussion

During 2021, eight redd surveys were competed between March 13 and June 8, a similar periods to past years (Table 3.1). In 2021, surveys were completed at flows that were well below the $20 \mathrm{~m}^{3} / \mathrm{s}$ upper limit for ideal surveys and only exceeded $20 \mathrm{~m}^{3} / \mathrm{s}$ on two days between the first and last surveys (Figure 3.2). The mean, minimum and maximum flow of the survey period in 2021 was within the range of past years (Table 3.1).

The goal of conducting bi-weekly surveys during the major portion of the spawning period was met for all eight surveys in 2021; across the entire survey period, the length of time between surveys ranged from 7-16 days, and averaged 12 days (Appendix 3.2, ). In previous years, the length of time between surveys has ranged from 6 to 37 days (Appendix 3.2).

Figure 3.3 Discharge ( $\mathrm{m}^{3} / \mathrm{s}$ ) in Coquitlam River at Port Coquitlam during Steelhead spawning period in 2021 (Water Survey of Canada station 08MH002). The red line represents the upper flow limit for ideal survey conditions. The red dots represent survey dates.

## 3. Adult Steelhead Escapement

### 3.2.1 Escapement and egg deposition

In 2021, a total of 214 novel redds were counted (Table 3.2). This represents a total escapement of 357 Steelhead (Table 3.2), which was a lower than average value for the 20052020 period (mean $=389$ ). The highest and lowest escapements occurred in 2006 (868 adults; Table 3.2) and 2020 ( 218 adults), respectively. Average Steelhead redd density in the study area of the Coquitlam River was 19.8 redds $/ \mathrm{km}$ in 2021, and ranged from $12-48$ redds $/ \mathrm{km}$ during 2005-2020 (Appendix 3.2). Among reaches and years, redd density ranged from 6-71 redds/km (Table 3.3). Spawning distribution during 2021 was similar in the lower reaches of the river ( 2 a and $2 \mathrm{~b}, 53 \%$ ) and higher in the upper reaches ( 3 and $4,47 \%$, Table 3.3), which is typical to the trend of equal or more spawning in the lower reaches for past years.

Table 3.2 Annual estimates of the total number of redds, redd/km, and the estimated number and density of female spawners, eggs, total escapement based on 1.2 females/redd, 3700 eggs/female and 2 spawners/redd. Peak counts represent the highest count of adults per year.

|  | Total <br> number <br> of redds | Redds <br> /km | Total <br> female <br> spawners | Total <br> egg <br> deposition | Eggs <br> /km | Total <br> adult <br> escapement | Peak <br> count |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 2005 | 224 | 20.7 | 187 | 691,000 | 64,000 | 373 | 22 |
| 2006 | 521 | 48.2 | 434 | $1,606,000$ | 149,000 | 868 | 95 |
| 2007 | 156 | 14.4 | 130 | 481,000 | 45,000 | 260 | 45 |
| 2008 | 178 | 16.5 | 148 | 549,000 | 51,000 | 297 | 44 |
| 2009 | 135 | 12.5 | 113 | 416,000 | 39,000 | 225 | 37 |
| 2010 | 200 | 18.5 | 167 | 617,000 | 57,000 | 333 | 60 |

| 2021 | $16 \%$ | $37 \%$ | $19 \%$ | $28 \%$ |

The principal sources of uncertainty in deriving Steelhead escapement estimates for the Coquitlam River from redd counts are the sex ratio and the average number of redds constructed by each female; error in escapement estimates will be directly proportional to error in either of these parameters.

There was no indication that the higher flows during 2021 led to redds becoming obscured by scour. This would have been apparent if individually marked redds were not detected in subsequent surveys. In 2020, all redds were confirmed during at least one survey after they were initially observed.

In 2021, there was a substantial number of redd counts at the beginning of the survey period and relatively few on the last survey. Ideally, counts on the first and last survey would be relatively low to indicate surveys spanned the entire survey period. The moderate count on the first survey suggests the assumption that surveys spanned the early spawning period was not clearly met and that spawning started earlier than past years. The relatively high count of live adults on the first survey ( 33 adults) compared to the peak count (49) also suggests an earlier start to spawning (Table 3.4). However, it is unlikely that the start of spawning was early enough that redds were obscured to the point they were undetected, given that all redds counted on the first survey were seen again on a later survey. This suggests spawning still started within two to three weeks of the survey start date. If spawning started prior to this, we would expect some redds to 'fade' and go undetected on the second survey. Across all years, no or minimal spawning ( $<5 \%$ of annual total) was observed by surveys prior to March 14. Excluding 2018 and 2020, $9 \%-18 \%$ of new redds were constructed by the end of March (Appendix 3.3). In 2018, there was increased spawning during March ( $37 \%$ of redds formed prior to March 31). The March spawning activity for 2020 falls between 2018 and the other years ( $24 \%$ of redds formed prior to March 31). The results for 2005 to 2020 suggest that Steelhead typically begin spawning

## 3. Adult Steelhead Escapement

in the Coquitlam River in early March but, with the exception of 2018 and 2020 that most spawning occurs ( $80-90 \%$ ) during a six-week period spanning early April to mid-May (Figure 3.4).

Table 3.4 Survey dates with raw counts of Steelhead redds, estimated new redds, and live adult counts for all surveys during 2021. Estimated new redds includes the sum of the raw count and the estimated number of redds that were constructed and then obscured by substrate movement prior to a scheduled survey, based on a redd survey life model. Appendix 3.3 lists this for all years.

| Year | Survey date | Days since <br> previous survey | Raw count <br> of new redds | Estimated \# <br> new redds | \# Live adults <br> observed |
| :---: | :---: | :---: | :---: | :---: | :---: |
| 2021 | 13-Mar | 0 | 5 | 5 | 35 |
| 2021 | 27-Mar | 14 | 20 | 20 | 49 |

Figure 3.4 Cumulative proportion of the total Steelhead redd count observed over time during 2020 (red) and 2005 2019 (grey).

Spawning Steelhead preferred mainstem habitat as compared to natural side channel and constructed off-channel habitat by a large margin during all survey years ( $83 \%-99 \%$ ). In 2020,

## 3. Adult Steelhead Escapement

$89 \%$ of the total number of redds were observed in mainstem sites. Average redd size was about $2 \mathrm{~m}^{2}$ during all years. Misidentification of resident trout or lamprey redds as Steelhead redds did not appear to be an issue, as the former were much smaller than Steelhead redds, and, in the case of trout, spawning was largely complete prior to the beginning of Steelhead spawning.

Increased base flows under Treatment 2 in 2009-2020 reduced the ability of the survey crew to spot adult Steelhead compared to previous years under Treatment 1 . Several sections of the river had increased turbulence that prevented ideal conditions for the observation of adults, and higher current velocities made it difficult for the snorkeler to slow down enough for careful observation. Nevertheless, the peak number of live adults observed on a single survey during Treatment 2 (37-148) was generally higher than during Treatment 1 (22-95, Table 3.2). During 2001-2004, when snorkel counts of adult Steelhead occurred as part of a larger survey of Steelhead escapement in BC Lower Mainland streams (BCCF, Lower Mainland Branch, data on file), the maximum number of adult Steelhead observed on any one survey ranged from 20-64. However, peak counts should be considered a less reliable index of year-to-year differences in total escapement compared to redd counts. Unadjusted live peak counts of winter Steelhead are often poorly correlated with actual escapement due to the lengthy spawning period, and the immigration and emigration of fish into the counting area over the course of the survey period (Korman et al. 2002). This is also the case on the Coquitlam River. Peak counts explain only $40 \%$ of the variability of escapement based on redd counts largely as a result of far fewer live counts than expected in 2006 (Figure 3.5).

Figure 3.5 Relationship between Adult Steelhead escapement estimates based on redd counts and peak counts of live adults during surveys 2005-2021 in the Coquitlam River.

No redds were found during the once-a-year reconnaissance survey of Reach 1 in 2021. Reach 1 is not included in the annual Steelhead redd survey, and thus redd counts for this section were not included in estimates of adult escapement for the purposes of continuity with past years.

## 3. Adult Steelhead Escapement

### 3.2.1 Redd survey life

In 2021, the period between surveys was typically short enough ( $\leq 16$ days) to assume that a negligible number of redds became obscured from one survey to the next, based on the evaluation of redd survey life during 2005-2021. The survey intervals were sufficiently short that redd life model estimated less than one additional redd for all surveys. Thus, the estimated number of new redds was considered equal to the raw count of new redds (Table 3.2). Between 2005-2020, 2006 was the only year where the number of redds estimated using the redd survey life model was substantially higher ( $21 \%$ ) than the unadjusted counts due to redds becoming undetectable over the 37-day gap between surveys that spanned the peak spawning period (Table 3.1). See Decker et al. 2010 for further discussion of trends in survey life.

### 3.3 Implications for hypothesis testing

The Coquitlam River is well suited to conducting Steelhead redd surveys and provides useful information for assessing the benefits to Steelhead of Treatment 1 and 2. Estimates of Steelhead spawner abundance and egg deposition based on total redd counts may be systematically biased high or low due to annual variation in number of redds each females constructs and the sex ratio but can still be expected to provide a useful index of recruitment.

## 4 Juvenile Salmonid Standing Stock

In 2006, the CC requested that a juvenile standing stock survey component be added to the monitoring program to provide estimates of total abundance in late summer for Coho and Steelhead fry (age-0+), and Steelhead parr (age-1+ and 2+) in the Coquitlam River mainstem. The purpose of this monitoring was that this data together with adult escapement and smolt abundance estimates, could be used to investigate freshwater production bottlenecks at specific juvenile life stages that may be related to specific habitat or flow issues. We conducted a feasibility study in 2006 to determine the best method for collecting annual juvenile standing stock data. The study compared three-pass removal electrofishing at 20 m long enclosed sites along one shoreline with night snorkeling counts at sites that extended across the entire stream channel (Decker et al. 2007). During 2007-2021 we proceeded with annual juvenile surveys based on night snorkeling counts, as this method proved to be the most effective for the purpose of estimating juvenile standing stocks (Decker et al. 2007). A multi-year mark-recapture study was also initiated in 2007 to provide estimates of snorkeling detection probability (percentage of fish present at a site that snorkelers detect), which is necessary to expand raw snorkeling counts to population estimates. A Hierarchical Bayesian Model (HBM) was use to provide estimates of juvenile standing stocks in the Coquitlam River during 2006-2021 (see Section 4.1.5).

During 2007-2021 we also conducted a separate 3-pass electrofishing survey (with input and assistance from Ron Ptolemy, MOE stock assessment). As per the COQMON-07 Terms of Reference, the electrofishing data was collected to provide a comparison of fish densities in specific habitats in the Coquitlam River with fish densities from similar habitats in other streams that were sampled using the same methods (BC MOE juvenile electrofishing database; see Ptolemy 2007). The collected electrofishing data was not used to estimate juvenile standing stocks in the Coquitlam River.

### 4.1 Methods

### 4.1.1 Study area

The study area extends 10.3 km from the Coquitlam Dam downstream to the Patricia Footbridge just upstream of the Lougheed highway (i.e., reaches 2a, 2b, 3, and 4; Figure 4.1), and includes all mainstem, braid and side-channel habitat. Natural and man-made off-channel habitats in Coquitlam River were not included, and juvenile fish populations in these habitats were therefore not included in juvenile standing stock values reported in this section or in Section 6.

### 4.1.2 Sampling design

We employed a two-stage sampling design (Cochrane 1977) to generate juvenile standing stock estimates by species and age-class for the Coquitlam River study area. The first stage consisted of a single-pass snorkeling count at each of the 12 index sites for 2007-2014 that were sampled each year with another 12 index sites added in 2014 increasing the sites surveyed to 24 for 2014-2021. The second stage consisted of conducting mark-recapture experiments at a
subsample of these sites to quantify snorkeling detection probability. A sufficient number markrecapture experiments ( $\mathrm{n}=23$ ) were completed by 2013 to adequately estimate observer efficiency. This study component no longer occurs. Fish abundance at each site was estimated by expanding the observed number of fish by the estimate of detection probability (global mean across all mark-recapture sites in all years for each species/size class). The abundance of fish in the remaining length of the Coquitlam River study area that was not sampled (i.e., total stream length $-\Sigma$ stream length index sites $1-12$ ) was estimated based on estimates of the mean and variance in fish density for the sampled sites. Total standing stock estimate for the study area was the sum of estimates for sampled and unsampled stream length.

Figure 4.1 Map of Coquitlam River showing juvenile standing stock study area, reach breaks and original 12 sampling sites.

## 3. Adult Steelhead Escapement

For this type of sampling design, uncertainty in the estimation of fish standing stocks is the result of both process error (spatial variation in fish abundance among sampling sites) and measurement error (error in the estimation of fish abundance within an individual site). Measurement error includes variation in detection probability caused by differences in fish behaviour and habitat characteristics among sites, and differences among snorkelers in their ability to spot and identify fish. The Hierarchical Bayesian Model (HBM) was used to estimate posterior distributions of the fish standing stocks, from which expected values (mean and median), and $95 \%$ credible intervals (Bayesian equivalent of confidence intervals) could be computed.

### 4.1.3 Night snorkeling

See Appendix 4.1 for a full description of night snorkeling methods. Snorkeling sites were chosen using a simple (non-stratified) systematic sampling design (SSS). During 2007-2013, the 10 sites originally selected in 2006 were re-sampled, and an additional two sites were added in Reach 4 to maintain a uniform sampling interval of $\sim 0.85 \mathrm{~km}$ (Figure 4.1 ). The additional 12 sites added in 2014 (for a total of 24 sites) were distributed equidistance between the existing sites. Each site was 25 m in length and spanned the entire stream channel, including a channels if more than one were present. Snorkeling surveys were scheduled for early September. Snorkeling counts were performed once at each site by a two-person crew. Counts were performed a four-hour period beginning 0.5 hours after dusk because numerous studies have shown that daytime concealment behaviour is common in juvenile salmonids (e.g., Bradford and Higgins 2000 and references therein). Near-shore habitats too shallow too shallow to view from an underwater position were visually surveyed on foot.

Snorkelers identified to species and visually estimated the fork lengths of all fish observed and recorded their observations in waterproof notebooks. To aid in the estimation of fish lengths, snorkelers drew ruled scales on the cover of their notebooks. Although there was no attempt to assess the accuracy of fish length estimates made by snorkelers, in two similar studies (Korman et al. 2011; Decker and Hagen 2009) in which some of the same snorkelers from this study participated, it was found that snorkelers could estimate juvenile fish lengths relatively precisely with little negative or positive bias ( $\mathrm{R}^{2}$ values for regressions of estimated versus measured fork length ranged from 0.94 to 0.97 ).

### 4.1.4 Mark-recapture experiments to estimate snorkeling detection probability

See Appendix 4.2

### 4.1.5 Estimation of fish standing stocks and mean densities

See Appendix 4.3 for a full description of methods. There are predominately three ageclasses of juvenile Steelhead (age-0+, 1+ and 2+) in the Coquitlam River during late summer; older fish are relatively uncommon and likely to be resident rainbow trout. We computed separate population statistics for each of the three age-classes, and also pooled age- $1+$ and age$2+$ Steelhead data to compute aggregate population statistics for Steelhead parr. Steelhead ages were estimated based on an analysis of length frequency histograms generated from both the

## 4. Juvenile Salmonid Standing Stock

electrofishing and snorkeling data, as well as from length-age data derived from Steelhead smolts from the Coquitlam River (see Section 5.2.2).

To estimate juvenile standing stocks for the entire study area, and to quantify uncertainty in these estimates, we relied on a modified version of an HBM originally developed by Korman et $a l$. (2010) to estimate juvenile Steelhead abundance in the Cheakamus River. To generate a standing stock estimate for a particular Steelhead age-class, the HBM sums estimates across the appropriate size-class strata.

To describe the precision of the standing stock estimates in this report, we have used percent relative error, which we computed as the average half credible interval (upper $95 \%$ credible limit minus the lower credible limit divided by two and then divided by the mean and expressed as a percentage Krebs 1999).

Fish/km was calculated by dividing the standing stock estimate by the total length of the Coquitlam River ( 10.3 km ). Fish $/ 100 \mathrm{~m}^{2}$ was calculated as the average density of the sampling sites. This is because the total area of the studied zone of the Coquitlam River is not assessed each year.

### 4.1.6 Day electrofishing survey

In 2021, we resurveyed four shoreline electrofishing sites previously sampled during 20072020. These sites were non-randomly chosen based on MOE protocols to represent fast-water habitats (riffle/cascades with relatively large mean substrate size) that were presumed to be ideal habitats for both Steelhead fry and parr (Ptolemy 2007). Sites were fully enclosed by upstream and downstream stop nets placed perpendicular to the shore, and a third offshore net that was placed parallel to the bank, and attached to the other two nets. Nets were held in place using a system of metal bipods, anchors and ropes, and cobbles and boulders placed along the bottom apron of each net. The offshore net was placed as far from shore as water depth and velocity permitted, usually 5-8 m .

Three-pass depletion electrofishing was conducted during daylight hours. Electrofishing was initiated at the downstream net, and consisted of a thorough search in an upstream direction, followed by a systematic sweep back towards the downstream net. Electrofishing sites were 'rested' for a minimum of one hour between passes to minimize decline in capture efficiency over subsequent passes (Bohlin and Sundstrom 1977). All salmonids captured were anaesthetized, identified to species, measured for fork length (nearest mm), allowed to recover and released back into the site following the completion of sampling. Population estimates were generated for age $0+$, $1+$ and $2+$ Steelhead (see Section 4.1.5, par. 1) and Coho at each site using a maximum likelihood (ML) algorithm (Otis et al. 1978).

### 4.1.7 Physical characteristics of snorkeling and electrofishing sites

We conducted simple habitat surveys to describe the physical characteristics of the sampling sites. At each site, depth was measured at five stations along each of three transects spanning the width of the site. During 2009-2021 we also estimated current velocity at each station using a

## 4. Juvenile Salmonid Standing Stock

propeller-type current meter. Stations were uniformly-spaced along transects, and transects were uniformly-spaced along the length of the site. We also recorded maximum depth, substrate composition (boulder, cobble, gravel, and fines as percentages of the site area), D90 and D50 (diameters of substrate particles for which $90 \%$ and $50 \%$, respectively, of the site area consist of smaller particles), site length, site width, cover (categories included: overhead vegetation, turbulence, deep water and boulder as percentages of the site area, undercut bank as a percentage of the combined length of the stream banks, and the total area of the site covered by wood debris). Other information collected for each site included location (UTMs), and water quality parameters (water temperature, pH , and total alkalinity).

### 4.2 Results

### 4.2.1 Night snorkeling

In 2021, night snorkeling surveys were completed over three days between Aug 24-27 at flows of $2.5-3.4 \mathrm{~m}^{3} / \mathrm{s}$ (WSC station 08MH002). Previous surveys were conducted at flows of $0.8-2 \mathrm{~m}^{3} / \mathrm{s}$ during Treatment 1 , and $2-7 \mathrm{~m}^{3} / \mathrm{s}$ during Treatment 2 . Water temperatures ranged from $19.6-21.9^{\circ} \mathrm{C}$ during 2021 , similar to previous years. In 2021, horizontal underwater visibility exceeded 4 meters at all sites. In past years, visibility has been adequate to good at all sites (2008, 3-4 metres; all other years, >4 metres). This is more than adequate for conducting snorkeling counts (Hagen et al. 2011) and within the range of conditions that detection probability experiments were conducted. Physical characteristics of the snorkel sites are listed in Appendix 4.4

### 4.2.1.2 Juvenile fish distribution and abundance

Abundance and density estimates for all years, species and age classes are listed in Appendix 4.6. The 2021 Coho fry abundance and $95 \%$ confidence intervals for the Coquitlam River mainstem was $28,049 \pm 29 \%$, which was below average compared with previous years (mean: 50,830; range: 18,450-91,367 fish, Figure 4.3). Precision of estimates has increased substantially with the doubling of the number of sampling sites from $\pm 38-44 \%$ for 2006-2013 to $\pm 30-31 \%$ for 2014-2021 (Figure 4.3).

Figure 4.2 Estimates of juvenile standing stock, and $95 \%$ confidence intervals by species and age class in Coquitlam River during 2006-2021. Estimates were derived from night snorkeling counts with the exception of 2011 Steelhead ( $0+$ ), which were based on electrofishing. Bar colour indicates cohorts that were reared entirely under Treatment 1 flows (red), Treatment 2 (green) or both (blue).

The 2021 Steelhead fry abundance of $21,743 \pm 32 \%$ was the lowest since surveys began in 2006 (mean: 48,878; range: 21,949-138,132 fish, Figure 4.2). However, the estimates may be biased low due to the over representation of fry smaller than the minimum size included in observer efficiency calibration experiments even though the other assumptions underlying the mark-recapture methodology were largely satisfied. In 2021, there was a higher proportion of fish less than 40 mm fork length (19\%) compared with the average from past years excluding the 2011 outlier year ( $5 \%$, Figure 4.3), which was the minimum size included in mark-recapture experiments ( $>40 \mathrm{~mm}$ ). This would have biased the fry estimate low since observer efficiency decreases with the size of fry (Korman et al. 2011) and yet we used the observer efficiency based
on fry with a fork length of $40-49 \mathrm{~mm}$ for smaller fry as well ( $<40 \mathrm{~mm}$ ). However, the underestimation may be relatively small considering that the proportion of observations for fry less than 40 mm from electroshocking - a more reliable sampling method for Steelhead fry - was far more similar to an average year than to 2011, when the large shift towards smaller sized fry led to a very unreliable snorkeling based estimate (see Schick et al. 2012). Relative precision was moderate in $2021( \pm 32 \%)$. The precision of fry estimates increased substantially since doubling the number of index site in 2014 ( $\pm 28-44 \%$ ) compared to prior years ( $\pm 37 \%-1790 \%$, Figure 4.3).

Figure 4.3 Length-frequency histogram (proportion of total catch less $<80 \mathrm{~mm}$ forklength) for Steelhead fry captured by electrofishing and counted during snorkeling in the Coquitlam River averaged for 2008-2020 and 2021 (data pooled for all sites). 2011 is also shown for electroshocking as an example of a year with considerable shift towards small sized fry.

The 2021 standing stock estimate of age- $1+$ Steelhead parr of $7,492 \pm 23 \%$ was below the average abundance since commencing snorkel surveys (mean: 8,824 ; range: 5,889-13,456 fish, 2006-2018, Figure 4.2). The density of age-1+ parr in 2021 was 727 fish/km. The 2021 standing stock estimate for age-2 Steelhead parr was $4,149 \pm 45 \%$. Mean density of age-2+ Steelhead parr in 2021 was 403 fish/km.

### 4.3 Implications for hypothesis testing

Standing stock monitoring was designed to provide stock-recruitment information at a shorter timescale than possible using smolt outmigration but also at a lower level of precision. As well, it was meant to inform on the distribution of abundance throughout the lower Coquitlam River. To this end, it is satisfying its objective. However, it was not intended as the primary metric for evaluating the fisheries benefits of Treatment 1 and 2.

Standing stock monitoring data based on snorkel surveys provides accurate abundance estimates for mainstem Coho, Steelhead fry and age-1+ Steelhead along with a consistent index of age-2+ Steelhead abundance. While the precision of 2006-2021 standing stock estimates are lower than the average for smolt and fry outmigration, it does provide useful information for distinguishing at what life-stage abundance may become limited by adult escapement versus rearing habitat availability.

## 4. Juvenile Salmonid Standing Stock

## 5 Smolt and Fry Outmigration

### 5.1 Methods

### 5.1.1 Coho and Steelhead smolt enumeration

In 2021, downstream migrating Coho and Steelhead smolts were captured at three locations in the Coquitlam River mainstem (RST2, RST3, RST4) using rotary screw traps (RST), and at the outlets of four constructed off-channel sites using full span weirs (Figure 5.1). Markrecapture data collected at RSTs were used to estimate smolt numbers for three mainstem reaches and for the entire Coquitlam River upstream of Port Coquitlam (Figure 5.1).

Our approach assumes all fish passing full span weirs are captured (capture efficiency $=$ $100 \%$ ) but that only a portion passing each RST site are caught (capture efficiency $\neq 100 \%$ ). We use variations of the Peterson two-sample mark-recapture method (Seber 1982) to estimate the proportion of fish passing each RST that are caught and not caught. This information is then used to adjust the catch from the RST site by the capture efficiency of the trap. For example, if an RST caught 50 of the 100 marked fish released upstream, the trap would have a $50 \%$ capture efficiency or that the trap captures half of the fish that pass by. And if a total of 1,000 fish were captured at that same trap, then we would estimate that another 1,000 fish passed without capture for a total estimate of 2,000 fish passing the trap. Our marking approach divides the outmigration period into a number of time periods (strata) that allows for individual estimates of capture efficiency for each stratum.

We estimated the number of Coho and Steelhead smolts passing each RST on the mainstem of the Coquitlam River using one or more analytical approaches that all rely on a two-sample mark-recapture method. In this study, smolts captured and marked at the weirs or upstream RSTs constituted the marking sample and smolts recovered at an RST represent the recovery sample. With stratified mark-recapture methodology, both the marking and recovery samples are stratified. For 2000-2017, we used the maximum likelihood (ML) model developed by Darroch (1961) and modified by Plante (1990) for stratified mark-recapture data. We refer to this model as the Darroch ML model. In 2018, we started using a Bayesian spline model using the package BTSPAS (Bayesian Time Stratified Petersen Analysis System) developed by Bonner and Schwarz (2014), which was run in the R statistical programming environment (R Core Team 2016).

Chum and Pink were only captured at RST2. Capture efficiency was estimated by marking a portion of captures, releasing them approximately 3 km upstream then recording the number of marked fish that were recaptured at RST2. See Appendix 5.1 for a full description sampling and analytical methods smolts and fry.

Figure 5.1 Map of the Coquitlam River showing constructed off-channel habitat sites, mainstem reach breaks and the locations of mainstem rotary screw traps (RSTs).

### 5.2 Results

### 5.2.1 Off-channel sites

In 2021, off-channel weirs were operational from March 1 to June 16 (Table 5.1), similar to most previous years. Trap operation has occasionally started in mid-February to monitor for early outmigration and as late as early April, as a consequence of logistical constraints related to the transition to a new contractor (2018). Traps operated continuously during this period. There were no trap breaches and no indications smolts were able to bypass weirs without capture.

Table 5.1 Start and end dates of trap operation, trapping season length, trapping days and percent season trapped for the 2021.

| Downstream |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
| RST trapping site | Start date | End date | Season <br> length | Trapping <br> days | $\%$ trapping |
| Reach 2 (RST2.2, chum, pink) | $3-1$ | $5-16$ | 77 | 70 | $91 \%$ |
| Reach 2 (RST2.4, coho, steelhead) | $3-14$ | $6-13$ | 92 | 89 | $97 \%$ |
| Reach 2 (RST2.5, coho, steelhead) | $3-14$ | $6-13$ | 92 | 89 | $97 \%$ |
| Reach 3 (RST3, coho, steelhead) | $3-14$ | $6-13$ | 92 | 89 | $97 \%$ |
| Reach 4 (RST4, coho, steelhead) | $3-14$ | $6-13$ | 92 | 92 | $100 \%$ |
| Archery Pond | $3-14$ | $6-13$ | 92 | 92 | $100 \%$ |
| Overland Ponds | $3-14$ | $6-13$ | 92 | 92 | $100 \%$ |
| Or Creek Ponds | $3-14$ | $6-13$ | 92 | 92 | $100 \%$ |
| Grants Tomb Pond | $3-14$ | $6-13$ | 92 | 92 | $100 \%$ |

Daily catches of Coho smolts at the off-channel weirs at the beginning of the trapping period were very low compared to catches during the peak of the migration at all off-channel trapping sites (Figure 5.3). Daily captures were relatively low by the end of trapping at all sites except Archery Ponds. For Archery Ponds, the three highest daily captures occurred during the last two weeks of trapping, but with low captured before and after these days. This supports the assumption that trapping included the entire smolt migration from Grant's Tomb, Or Creek and Overland off-channel areas but less so for Archery Ponds due to the possibility substantial outmigration continued after trapping ended mid-June. However, even if this did occur, posttrapping outmigration from Archery Ponds is unlikely to have a meaningful impact on offchannel and total river abundance estimates. For these reasons, we consider that weir counts likely represent Coho smolt outmigration from off-channel sites during 2021. For Steelhead, daily captures were too low and sporadic to assess whether off-channel weir operation spanned the entire outmigration period (Figure 5.4). Observed mortality for Coho was $0-1 \%$ at the offchannel weirs. There were no Steelhead mortalities at the four off-channel weirs.

Figure 5.3 Daily catches of Coho smolts at downstream weirs in four off-channel sites (pooled data) and at three rotary screw trapping locations in the Coquitlam River mainstem in 2021. See Table 5.1 for start and end dates for individual trapping sites.

Steelhead smolts

Figure 5.4 Daily catches of Steelhead smolts at downstream weirs in three off-channel sites (pooled data) and at three rotary screw trapping locations in the Coquitlam River mainstem in 2021. See Table 5.1 for start and end dates for individual trapping sites.

In 2021, an aggregate total of 1,582 Coho and 45 Steelhead smolts were captured at the downstream weirs as they outmigrated from the Overland, Or Creek, Archery Ponds and Grant's Tomb off-channel sites (Table 5.2). There was no evidence that the 2021 estimates were biased due to smolts evading capture or from the trapping period not including the majority of the outmigration period.

Table 5.2 Summary of estimated smolt numbers and densities by species in 2021 for four off-channel sites, for reaches 2-4 of the Coquitlam River mainstem, and for the total Coquitlam River mainstem including and excluding the off-channel sites.

| Site | Length <br> (km) | $\begin{gathered} \hline \text { Area } \\ \left(\mathrm{m}^{2}\right) \end{gathered}$ | N smolts | CI (+/-) | CI (\%) | Density |  |

| Mainstem |  |  |  |  |  |  |  |
| Reach 2, Coquitlam River | 3.2 | 83,778 | - | - | - | - | - |
| Reach 3, Coquitlam River | 2.7 | 46,920 | - | - | - | - | - |
| Reach 4, Coquitlam River | 1.6 | 19,200 | 1,763 | 906 | 51\% | 9.2 | 1,102 |
| Total Mainstem | 7.5 | 149,898 | 5,809 | 911 | 16\% | 3.9 | 775 |
| Coquitlam R.incl. off-channel s: | 7.5 | 171,034 | 5,854 | 911 | 16\% | 3.4 | 781 |
| Coquitlam R.incl. off-channel s: | 7.5 | 171,034 | $\begin{gathered} \text { Chum } \\ 4,900,955 \end{gathered}$ | 268,845 | 5\% | 2,865 | 653,461 |

The mean weighted density of Coho smolts in the off-channel sites was 7.5 smolts $/ 100 \mathrm{~m}^{2}$ while Steelhead smolt density was 0.2 smolts $/ 100 \mathrm{~m}^{2}$ (Table 5.2). In terms of areal density, trends across years and flow treatment periods for Coho were flat for Or Creek Ponds and declining for Archery Ponds, Grant's Tomb, and Overland (Figure 5.5a). The density of Steelhead has been variable at the off-channel sites, with no clear trends across years (Figure $5.5 b$ ). Across all years, $17 \%-68 \%$ for Coho and $0.3 \%-9 \%$ for Steelhead of production for the entire Coquitlam River upstream of RST2 originated from the constructed off-channel sites.

Figure 5.5 a-b Areal density of Coho and Steelhead smolt (smolts/100m2) in four constructed off-channel habitats along the Coquitlam River and for all four combined (Total) previous to Treatment 1 (1996-2000), Treatment 1 (2002-2008), when smolt cohorts reared under both treatments (2009) and Treatment 2 (2010-2021). Years with zero fish represent those when the off-channel habitats were not in operation or were not monitored.

### 5.2.2 Coquitlam River mainstem

### 5.2.2.1 Discharge and trap operations

In 2021, fry trapping at RST2 began March 1 and smolt trapping began March 14 at all other sites (Table 5.1). Discharge in the Coquitlam River during the spring trapping period was similar to other Treatment 2 years, with the exception of 2018 when discharge from the LLO was increased from $3.5 \mathrm{~m}^{3} / \mathrm{s}$ (April) and $2.9 \mathrm{~m}^{3} / \mathrm{s}$ (May) to $8 \mathrm{~m}^{3} / \mathrm{s}$ as part of the Kwikwetlem Sockeye Restoration Program (KSRP). Daily mean flows exceeded the $12 \mathrm{~m}^{3} / \mathrm{s}$ limit for Chum fry trapping on seven occasions and exceeded the $20 \mathrm{~m}^{3} / \mathrm{s}$ limit for Steelhead and Coho smolt trapping on two occasions (Figure 5.6). Due to flows exceeding the trap capacity, fry trapping operations at RST2 were suspended for one day on two occasions and two days on two occasions for a total of six lost trapping days during the 89 -day monitoring period ( $96 \%$ of days with trapping). Smolt trapping at all three RST sites was near continuous. Traps operated $97 \%$ of the monitoring period at RST2 and RST3, and the entire period at RDT4. Trap operations were suspended for two one-day periods at RST2 and RST3.

Figure 5.6 Mean daily flows in Coquitlam River at Port Coquitlam during the smolt and fry trapping period in 2021. (Water Survey of Canada, stn. 08MH002). The maximum discharge for operating the smolt traps is shown by the red line ( $20 \mathrm{~m}^{3} / \mathrm{s}$ ) and for the fry trap by the blue line ( $12 \mathrm{~m}^{3} / \mathrm{s}$ ).

Figure 5.7 Daily catches of Chinook fry, Chum fry, Coho fry, Pink fry, Steelhead parr and Sockeye smolts at the RST2 trapping site in Reach 2 in the Coquitlam River in 2021. See Table 5.1 for start and end dates of downstream trapping.

Daily catches of all species at the beginning and end of the trapping period were very low compared to catches during the peak of the migration (Figures 5.3-5.4, 5.7). This suggests that population closure was largely met for all species.

Stratified mark-recapture data (catch tables) used to generate estimates of the number of Coho and Steelhead passing each RST site are shown in Appendix 5.3.

### 5.2.2.2 Coho

Table 5.1 lists estimates of mainstem smolt production for Reach 2-4 individually, as well as for all three reaches combined, with and without off-channel sites.

Table 5.3 Differences in capture efficiency (proportion of marked smolts that were recaptured) for Coho and Steelhead from off-channel sites and the Coquitlam River mainstem at three rotary screw traps (RSTs) sites in the Coquitlam River mainstem in 2021. Stratified marking periods were pooled prior to testing (see Equation 5.1). Equal capture efficiency for mark groups was tested using Fisher's exact test. $\mathrm{P}<0.05$ indicates a significant difference in capture efficiency.

|  |  | Capture efficiency |  | Fisher's exact |
| :--- | :---: | :---: | :---: | :---: |
| Species | Recapture site | Mainstem <br> mark group | Off-channel <br> mark group |  |
| Coho | RST 2 | 0.28 | 0.29 | 0.65 |
| Coho | RST 3 | 0.05 | 0.06 | 0.21 |
| Coho | RST 4 | 0.44 | 0.44 | 0.84 |
| Steelhead | RST 2 | 0.14 | 0.05 | 0.07 |
| Steelhead | RST 3 | 0.01 | 0.00 | 0.54 |
| Steelhead | RST 4 | 0.25 | 0.19 | 0.44 |

At RST4, capture efficiency was identical for off-channel and mainstem mark groups ( $44 \%$, Fisher's exact test, $\mathrm{P}=0.84$, Table 5.3). For this reason, we used both mark group for the estimate of mainstem smolts passing RST4. Using BTSPAS, we estimated that 1,852 Coho smolts ( $95 \% \mathrm{CI}: \pm 11 \%$ ) passed the reach 4 trapping site (Table 5.4), which also represents the smolt production for this reach. Note precision from BTSPAS is represented by $95 \%$ credible intervals, which in this report are considered analogous to $95 \%$ confidence intervals from the Darroch ML estimator used prior to 2018. Precision of the 2021 estimate is near the mean for Treatment 2 prior to $2018( \pm 8 \%)$ even though there were relatively high capture efficiency and numbers of recaptured smolts. We expect lower precision using BTSPAS since it includes the additional uncertainty when estimating abundance during strata with low recaptures, which wasn't included in the Darroch ML estimator as well as when incomplete sample requires splinefitting for the estimates.

Table 5.4 Summary of estimated numbers of Coho, Steelhead and Chum smolts passing the three RST trapping locations (not reach estimates) in the Coquitlam River mainstem in 2021. Mark group indicates the location where fish were initially captured and marked. Also shown are numbers of marked (M), recaptured (R) smolts, unmarked captures $(\mathrm{U})$ and estimated capture efficiencies $(\mathrm{R} / \mathrm{M})$.

| Species | Site | Mark <br> group(s) | M | R | U | Capture efficiency | $\begin{gathered} \mathrm{N} \\ \text { mainstem } \\ \text { smolts } \end{gathered}$ | CI (+/-) | CI (\%) |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Coho | RST 2 | all | 2,772 | 790 | 1,966 | 28\% | 9,446 | 627 | 7\% |
|  | RST 3 | all | 2,017 | 113 | 370 | 6\% | 8,893 | 2,852 | 32\% |
|  | RST 4 | all | 781 | 341 | 765 | 44\% | 1,852 | 208 | 11\% |
| Steelhead | RST 2 | all | 1,048 | 143 | 680 | 14\% | 5,809 | 911 | 16\% |
|  | RST 3 | all | 327 | 2 | 12 | - | - | - | - |
|  | RST 4 | all | 305 | 74 | 270 | 24\% | 1,763 | 906 | 51\% |
| Chum | RST 2 | RST 2 | 20,430 | 2,157 | 83,918 | 11\% | 4,900,955 | 268,845 | 5\% |

At RST3, capture efficiency using marked off-channel and mainstem Coho smolts were not significantly different ( $4 \%$ and $5 \%$, respectively, Fisher's exact test, $\mathrm{P}=0.20$; Table 5.3). Considering this, we used both mainstem and off-channel mark groups to estimate that $8,893 \pm$ $32 \%$ mainstem smolts passed RST3 (Table 5.4). Once smolts from reach 4 were subtracted, we estimated the production from reach 3 to be $7,041 \pm 41 \%$ smolts. The low precision of the reach 3 estimate is a product of lower recaptures at RST 3 combined with the reduction due to subtracting one estimate from another.

At RST2, capture efficiency was not significantly different for the mainstem mark and offchannel mark groups ( $28 \%$ and $29 \%$, respectively, $\mathrm{P}=0.65$; Table 5.3). Using both mark groups, we estimated the total number of mainstem smolts that passed RST2 was $9,446 \pm 7 \%$ (Table 5.4). The smolt production estimated for reach 2 was $553 \pm 528 \%$ smolts, once the contribution from reaches 3 and 4 were removed. This estimate is low compared to past years and highly uncertain.

We estimated smolt production for the entire mainstem upstream of RST2 at 9,446 $\pm 7 \%$ smolts and $11,028 \pm 6 \%$ when including the production from off-channel habitats. Precision of the mainstem estimate is similar to past Treatment 2 years (mean $= \pm 10 \%$ ). This is due to adequate recaptures at RST2 at the low number of missed trapping days.

Average estimated Coho smolt density in the Coquitlam River mainstem was 6.3 smolts/ 100 $\mathrm{m}^{2}$ and 6.4 smolts $/ 100 \mathrm{~m}^{2}$ including the off-channel sites. Linear Coho density was 15 -fold higher in reaches $3(2,608$ smolts $/ \mathrm{km}$; Table 5.2), than in reach $2(173$ smolts $/ \mathrm{km})$ and twofold higher than reach $4(1,158$ smolts $/ \mathrm{km})$. The precision of estimates for individual reaches ranged from $\pm 11 \%$ for the estimate for reach 4 , to $\pm 528 \%$ for the smolt estimate for reach 2 (Table 5.2). This is similar to 2018-2020 for reach 4 but lower for reach 2, largely due to the lower smolt estimate and lower precision of the reach 3 estimate. This is still in the range to

## 5. Smolt and Fry Outmigration

provide useful information for evaluating flow effects. The lower precision for 2018-2021 are a product of the way BTSPAS includes the uncertainty when abundance for a stratum with missing mark-recapture data is based on fitting the spline and during strata with few recaptures. These uncertainties existed prior to 2018 but Darroch ML estimator did not have the capacity to estimate it.

Abundance estimates across all years and reaches for Coho are reported in Appendix 5.4. The analysis of abundance estimate trends across all study years and low treatment periods is included in Section 6.

### 5.2.2.3 Steelhead

At RST4, we used both mark groups to estimate that $1,763 \pm 51 \%$ Steelhead smolts passed RST4 (Table 5.4). We used both mark groups since capture efficiency was not significantly different ( $25 \%$ and $19 \%$, respectively, $\mathrm{P}=0.44$; Table 5.3 ). The lower capture efficiency of recent years continued in 2021 ( $18 \%$, Table 5.4), and is reflected in the moderate precision of the estimates. Since recaptures at RST4 depend on the number of smolts marked at this site, released upstream and then recaptured, low capture efficiency reduced both the number marked and the proportion of those recaptured. The capture efficiency was similar to 2019-2020 (13\% and $18 \%$ ), and higher than for $2018(2 \%)$, but far lower than other prior years (30-60\%). The increased capture efficiency from 2018 was due to a return to using the larger trap (diameter $=$ 2.4 m ) and lower dam discharge.

At RST3, only two of the 327 Steelhead smolts marked at RST4 were recaptured. Due to this, we are unable to estimate the number of Steelhead smolts passing the trap. Capture efficiency at RST3 decreased to $1 \%$ or less in 2020, a substantial reduction from 15-20\% prior to 2018. The continued low capture efficiency since 2018 is likely a product of the move to a new location, which lacks the well-defined thalweg that concentrates fish within a portion of the channel. The RST3 site was moved approximately 200 m upstream due to changes in site access. The channel width and depth at the new site was considered insufficient for traps larger than 1.5 m.

At RST2, capture efficiency was not quite significantly different for mainstem and offchannel mark groups ( $14 \%$ and $5 \%$, respectively, $\mathrm{P}=0.07$; Table 5.3) but as with previous years, this was largely a result of insufficient power to detect a difference. We used both mark groups for the estimate that $5,809 \pm 16 \%$ mainstem Steelhead smolts passed RST2. This also represents the estimate of mainstem production for the Coquitlam River upstream of RST2. When we included Steelhead from off-channel habitats, the estimate for all areas upstream of RST2 was $5,845 \pm 16 \%$ (Table 5.2). Precision is at the high end of the range during Treatment 2 prior to 2018 (range: $\pm 9 \%$ to $38 \%$ ) and a large improvement from 2018 ( $\pm 76 \%$ ). This is due to sufficient numbers of recaptures during the period when the majority of outmigration occurred.

With only two lost trapping days that were outside of the peak migration period, we did not flag any strata as 'bad', which triggers spline fitting in place of missing data, as this would have minimal impact on the mainstem estimate.

## 5. Smolt and Fry Outmigration

Average Steelhead density in the Coquitlam River mainstem was 775 smolts / km (Table 5.2). Smolt density in reach 4 was considerably higher than the average of the entire mainstem as has been the case during Treatment 2 ( 1,102 smolts / km).

Figure 5.8 Length-frequency histogram for unmarked Steelhead captured in the Coquitlam River in 2021 (data pooled for all trap sites).

We assumed all Steelhead with a fork length of $120-230 \mathrm{~mm}$ to be smolts. As in previous years, 120 mm corresponded to the minima between two defined modes representing age- $1+$ and age- $2+$ and older juveniles, respectively (Figure 5.8). This was corroborated by scale samples collected for Steelhead in this size range during 2005-2021 (Appendix 5.3). Scale analysis of 865 individuals indicated a broad overlap (130-188 mm) in the absolute ranges in fork length for age- 2 and age- 3 smolts, but most smolts greater than 160 mm in length were age- 3 (Appendix 5.5). Age-4 smolts were also present in the scale sample, ranging in length from 171 mm to 222 mm . Age- 4 smolts comprised $5 \%-10 \%$ of smolts $165-194 \mathrm{~mm}$ fork length and $30 \%-60 \%$ of smolts $195-220 \mathrm{~mm}$. To estimate Steelhead adult-to-smolt survival for the 2005-2018 escapement years (the broods of later escapement have yet to smolt), we used age-2/age- 3 length cut-offs of 160-170 mm (depending on the year) to estimate the proportions of age- 2 smolts in the smolt populations. The proportion of age- 2 smolts ranged from $50 \%-67 \%$ among years.

Abundance across all years and reaches for Steelhead are reported in Appendix 5.4.
Analysis of abundance trends across years or by flow treatment period are included in Section 6.

### 5.2.2.4 Chum and Pink

Chum and Pink fry were trapped from March 1 to May 16 at the RST2 location in reach 2 (Table 5.1). For Chum capture efficiency varied from $5.8 \%-14.2 \%$ across the six weekly marking periods (Appendix 5.3), and averaged $11 \%$ (Table 5.4). Out outages, did not occur when there were sufficient daily captures to mark, and were prior to peak outmigration. Thus, we didn't we didn't flag any strata as 'bad', which would trigger BTSPAS to use spline-fitting to estimate the number of unmarked captures for a stratum. During 2021, an estimated 4.9 million $\pm$ $5 \%$ Chum fry (Table 5.2) migrated past the RST2 trapping site. The estimated density in the mainstem of the Coquitlam River for Chum was $653,461 \mathrm{fry} / \mathrm{km}$ (Table 5.2). We consider this a relatively accurate estimate. Trap operation was also similar to most prior years and included the majority of the outmigration period (Figure 5.4). 2021 was a 'non-Pink year'. Captures were too low to generate estimates.

### 5.2.2.5 Sockeye/Kokanee

In 2021, catches of Sockeye smolts at RST 2-4 were 235, 17 and 423; respectively (Table 5.5). No mortalities occurred at RST 2-4. Sockeye captured each year at all traps during Treatments 1 and 2 have ranged from 10's of fish to several hundred (2005-2007). 2021 captures are the highest thus far. While Sockeye have not been included in mark-recapture component needed for accurate abundance estimates, the 2021 captures are likely sufficient to consider this in future years.

Table 5.5 Captures of Chinook and Coho fry, Steelhead parr and Sockeye/Kokanee during 2021 at RST 2-4.

| Site | Chinook smolts/fry | Coho fry | Steelhead parr | Sockeye smolts |
| :---: | :---: | :---: | :---: | :---: |
| RST 2 | 1,018 | 21,498 | 56 | 235 |
| RST 3 | 2 | 1 | 11 | 17 |
| RST 4 | 15 | 3 | 15 | 423 |

### 5.2.2.6 Chinook

In 2021, 1,018 Chinook juveniles were captured by the two smolt traps at the RST2 one fry trap at RST2 (Table 5.5). As in past years, there was no attempt to distinguish between the ageclasses and they were not included in the mark-recapture program, which would have been necessary to estimate the number of outmigrants.

### 5.2.2.7 Coho Fry

In addition to Coho smolt production, an additional 21,498 Coho fry were captured at the RST2 fry trap in 2021 (Table 5.5). Fry catch has ranged from 2,200-30,000 since 2008. As with previous years, there was no attempt in 2021 to include them in the mark-recapture program or estimate the number of outmigrants.

### 5.3 Discussion

Tables 6.4 a and 6.4 b in the next section provide estimates of annual escapement, juvenile standing stocks, and smolt production for the Coquitlam River upstream of RST2, along with survival rates from one life stage to the next.

### 5.3.1 Assumptions of the study design

We assumed all two year and older Steelhead (120-230 mm in length) were smolts. However, there was probably a small proportion of smaller Steelhead in this size range, which were likely parr that were dispersing to downstream habitats, and would ultimately be smolting at age-3, or even age-4 (Withers 1966). As well, some of the larger fish in this size range were likely mature residents. In past years we excluded a small number of fish that the trapping crew identified as being resident Rainbow Trout based on cryptic colouring and heavy spotting as opposed to the typical silvery colouration of a smolt. A number of these fish were confirmed to be sexually mature males or females as they released milt or eggs when light abdominal pressure was applied. However, the vast majority of Steelhead that were captured and recorded as smolts were silvery in appearance (e.g., >97\% in 2002 and 2005 when physical characteristics were categorized for all Steelhead captured). Moreover, the average fork length of Steelhead smolts during 1996-2020 varied from 154 mm to 171 mm , which is in good agreement with the expected mean length at ocean entry for Steelhead stocks in the North Pacific ( 160 mm ; $\mathrm{CV}=10 \%-15 \%$; Burgner et al. 1992).

We have assumed that captures of Steelhead parr represent within-river movement rather than outmigration. This has not been confirmed during this monitoring program. If Steelhead do exit the study reaches as parr, this would represent unaccounted for juvenile production.

For Chum estimates, the primary assumption was the capture efficiency estimated from the 1-3 days per weekly strata reflects the capture efficiency during the remaining days, when no marked fish passed the trap. To minimize the extent of this assumption, the number of release days was increased from one to 2-3 days per weekly strata period from the single release prior to 2019.

### 5.3.2 Reliability of estimates and implications for the flow experiment

Results to date suggest that, for the most part, the downstream trapping program in its current form is adequate for the purposes of generating sufficiently precise and reliable estimates of smolt and fry abundance for all species to meet COQMON-07 objectives.

Higgins et al. (2002) demonstrated that the statistical power to detect differences in fish production in the Coquitlam River under different flow regimes was strongly influenced by the precision of annual estimates of smolt abundance. Specifically, they showed that for a simulated 12 year-long experiment, power ( $\beta$ ) decreases significantly over a range of increasing observation error ( $\sigma_{\mathrm{sm}, \mathrm{o}}$ in their paper) from a high of $\beta$ : 0.6-0.7 with no observation error to a low of $\beta: 0.3$. While this falls short of the goal of 'moderate' power ( $\beta>0.8$ ), the study suggested that there was relatively little drop in power at smolt observation error levels up to 0.10.2 , which expressed as a $95 \%$ confidence interval are $\pm 20 \%$ to $\pm 40 \%$ of the estimate.

The precision of the 2021 Coho smolt abundance estimate in the Coquitlam River mainstem was high ( $95 \% \mathrm{CI}: \pm 6 \%$ ) and at the high end of the estimates for $2000-2020$ ( $95 \% \mathrm{CI}: \pm 6 \%$ $14 \%$ ). It is well above the theoretical optimal value of $\pm 20 \%$ predicted by Higgins et al (2002). Precision of the 2021 mainstem Steelhead smolt estimate was moderate ( $95 \% \mathrm{CI}: \pm 16 \%$ ), at the upper half of the range of estimates since $2000(95 \% \mathrm{CI}: \pm 11 \%-37 \%)$ and above the predicted theoretical optimum. For both Steelhead and Coho smolts, this was the result of maximizing the number of recaptures at RST2 by marking smolts at RST2-4 for Steelhead and RST3-4 for Coho combined with relatively high capture efficiency at RST2. It was also due to the near continuous trap operation, which minimized the reliance on spline-fitting to estimates abundance during periods of incomplete trapping.

The precision of population estimates for Chum fry at the RST2 in 2021 was high ( $95 \%$ CI: $\pm 5 \%$ ) compared with previous years using rotary screw traps ( $95 \% \mathrm{CI}$ : $6 \%-18 \%$ during 20082020).

## 6 Fish Productivity during Treatment 1 and 2

The COQMON-07 uses a Before-After (BA) experimental design where fish metrics (i.e. abundance, survival, productivity) measured under flow Treatment 1 conditions are compared to those under Treatment 2. The expectation of the Consultative Committee (CC) was that increased base flows (all months except June and July) would benefit spawning and/or juvenile rearing of target species (Table 1.1, Figure1.1). The CC chose an empirical approach to evaluating the benefits of either flow regime. Thus, the primary objective of monitoring is to address the management question:

What are the fisheries benefits of Flow Treatment 1 (2FV) and Treatment 2 (STP6)?
The analysis approach to evaluate the fisheries benefits for Coho and Steelhead relies upon overall smolt production and to a lesser degree on standing stock estimates and survival from one age-class to another. For Pink and Chum salmon, we use egg-to-smolt survival (productivity) as the main metric for the evaluation. We break the evaluation process into two questions.

1. Did fish production or productivity change between Treatment 1 and 2 , and by how much? We used the 2 -tailed T-test $(\alpha<0.05)$ to test for a statistically significant change in Steelhead and Coho smolt yield. To evaluate the biological significance of the change, we used the percent change in productivity between Treatment 1 and 2 (effect size). To evaluate whether Chum and Pink Salmon productivity changed between treatments, we used the Analysis of Covariance (ANCOVA) to test whether the flow treatment was a statistically significant predictor of productivity ( $\alpha<0.05$ ). We also check the assumption that any change in productivity was due to the change in flow treatments by comparing abundance trends in the Coquitlam River to other south coast rivers that didn't experience changes in flow regulation during this time period. These "control" rivers reflect abundance changes due to factors unrelated to the change from Treatment 1 to Treatment 2. Note that the reliability of the BA experimental design depends on satisfying the assumption that, in this case, flow treatment was the dominant influence of productivity. For the Coquitlam, the expectation was that Treatment 2 flows would have a neutral to positive effect on smolt production, and thus, the between treatment increase would be similar (neutral) or larger (positive) than the change that happened over a similar time period in the control streams. Appendix 6.1 list the criteria for inclusion in the analysis. Appendix 6.2 lists the rivers used. Appendix 6.3 list the annual abundance estimates for each river.
2. What were the main factors impacting freshwater survival? For this we compared the effectiveness of Ricker stock-recruitment models with and without a covariate to explain year-to-year changes in juvenile abundance. Covariates include flow treatment, season specific flow metrics and for Coho, stranding estimates. With this, we can examine the influence of stock size (e.g. adult spawners), density dependent effects, and in combination with the covariate effects (e.g. flow treatment). This allows for comparisons of the models using the deviance information criterion
(DIC). DIC is similar to the Akaike information criterion used to compare support for different models (Burnham and Anderson 2002) but is more compatible with the hierarchical modeling method used in this analysis. In this context, models differ in the variable used to explain the fish data and whether one or two variables is included. Models with more variables may fit the data better but variable estimates will be less precise. The most parsimonious model from a group of models is the one which exhibits the best trade-off between fit and precision, and will have the lowest DIC value. Models with $\Delta$ DIC $>2$ are considered to have strong support, 2-7 moderate support and $>7$ low support. We also evaluated the overall effectiveness of the model by the amount of variation explained by a model $\left(\mathrm{R}^{2}\right)$. This is important since the model with most support (lowest DIC value) may not be a useful model if it explains only a small amount of the variation. For example, a model that explains $80 \%$ of the variation is more useful than one that explains $10 \%$. To evaluate the covariate effects on survival, we fit the following covariate Ricker stock-recruitment model to the data,
$R_{t}=S_{t} \cdot e^{a+\beta \cdot S_{t}+\gamma \cdot X_{t}}$
Eq 6.1
where $\mathrm{R}_{\mathrm{t}}$ is the abundance of one life stage (e.g., outmigrating Chum fry) in year $t, \mathrm{~S}$ is the estimated abundance of the previous life stage (e.g., Chum spawners ), $\alpha$ is the $\log$ of the maximum survival rate when there are no density or flow effects (productivity), $\beta$ is a density-dependent effect, and $\gamma$ is the effect of flow covariate $\mathrm{X}_{\mathrm{t}}$. The product of $\gamma$ and $\mathrm{X}_{\mathrm{t}}$ therefore represents the vertical shift in the stockrecruitment curve in $\log$ space in year $t$ due to the value of the flow covariate in that year. As $X_{\mathrm{t}}$ is a standardized annual covariate value ( $X_{t}=\frac{x_{t}-\mu}{\sigma}$ ), this formulation results in a base recruitment curve at the mean level of the covariate value, since the standardized value would be 0 in this case (thus $\exp \left(\gamma \cdot X_{t}\right)=1$ ). A variety of flow covariates were computed using mean hourly discharge records at the WSC Port Coquitlam gauge.

The WUP did not specify the amount of change in fish production or productivity to conclude that a meaningful amount had occurred. The Consultative Committee predicted increases in abundance ranging from $10 \%-100 \%$ (Higgins et al. 2002). The expectation of the study was that it would have an $80 \%$ probability of detecting a $50 \%$ change in abundance, but this was not to say that smaller changes would not be of interest to the CC and in decisions about future flows.

### 6.1 Treatment 1 and 2 flows

Treatment 1 and 2 discharges are based on releases from the low level outlet gates (LLOG) at Coquitlam Dam. The LLOG releases for Treatment 2 were categorized as either targeted or minimum discharge. Releases are based on targeted levels other than during periods of limited

## 6. Fish Productivity during Treatment 1 and 2

reservoir capacity or inflows based on a set of rules set out in the Water Use Plan. Generally, targeted releases were higher throughout the year compared with Treatment 1 with the exception of June and July, which were lowered slightly (Table 1.1). Minimum release levels were still higher than Treatment 1 minimums for October to February but similar to Treatment 1 levels for March to September.

Based on flows measured at the Water Survey of Canada station at Port Coquitlam, the increased release from the LLOG during Treatment 2 resulted in higher minimum flows for all months but June-August (Figure 6.1). The absence of an increase in minimum flows for August reflects the frequency that LLOG releases were based on minimum levels rather than on targeted levels. Mean discharge increases were most pronounced during February-April and SeptemberOctober. This timing corresponds to periods with increased targeted releases as well as relatively low inflows from tributaries below the dam. The difference between minimum and mean discharge was most pronounced during late fall and winter when the contribution from tributaries and spill events represents a large portion of total flow. For the months with higher minimum flows, flows were also more stable during Treatment 2 (Figure 6.1).

Another notable difference between Treatment 1 and 2 was the increase in rampdown events, which occurred almost entirely as a consequence of the monthly change in releases from the LLOGs. While the number of unscheduled rampdowns following higher flow events was similar for each treatment, there were from three to six scheduled rampdowns each year during Treatment 2 while none of comparable size occurred previously (MacNair 2018).

Figure 6.1 Monthly discharge statistics for the Coquitlam River during Flow Treatment 1 (2000-2008) and Treatment 2 (2009-2021) measured at Port Coquitlam (Water Survey of Canada, stn. 08MH141) including monthly mean and minimum discharge as well as the coefficient of variation in monthly mean discharge.

### 6.2 Coho

### 6.2.1 Off-channel smolt abundance

Smolt production from the four constructed off-channel habitats ${ }^{1}$ was not considered one of the primary metrics for evaluating the impact of dam regulated flows on freshwater productivity. This is because 1) flows in off-channel areas are stabilized by groundwater inputs and regulated mainstem intakes and 2) continued maintenance of off-channel areas has a large impact on productive capacity. This is not to say that productivity in these areas is unaffected by mainstem flows, but that effects could be less than in the mainstem and, more importantly, mainstem flow effects could be confounded with other factors impacting the productivity of off-channel areas. Production from the four off-channel habitats is reported here because it represents a considerable portion of smolt production for the Coquitlam River and changes in productivity could have population level consequences.

Figure 6.2 Annual Coho smolts density for four constructed off-channel habitats connected to the Coquitlam River. The colours of the bars reflect the flow treatment period of the cohort outmigrating during that year: pre-Treatment (purple), Treatment 1 (red), both treatment conditions (teal), Treatment 2 (green).

The four monitored off-channel habitats represent about $10 \%$ of available habitat in the Coquitlam River study area and supported from $17 \%$ to $77 \%$ of the overwintering Coho smolt population during 2000-2021. Since monitoring began in 1995, Total off-channel smolt density has generally declined in all four areas but the decline was most pronounced in Grant's Tomb and Overland Channel (Figure 6.2). Mean off-channel smolt density decreased from 28 smolts $/ 100 \mathrm{~m}^{2}$ during Treatment 1 to 13 smolts $/ 100 \mathrm{~m}^{2}$ during Treatment 2 (2-tailed t -test, $p=$ 0.01 ). While constructed off-channel habitat may represent relatively productive Coho habitat in the Coquitlam River, the smolt densities in Coquitlam River off-channel sites were below the

[^1]6. Fish Productivity during Treatment 1 and 2
average densities reported for constructed side-channels and ponds in other Pacific Northwest streams ( 67 and 69 smolts $/ 100 \mathrm{~m}^{2}$, respectively; Koning and Keeley 1997).

### 6.2.2 Mainstem smolt abundance

During 2000-2021, the Coho smolt yield for the 7.5 km long section of the lower Coquitlam River mainstem upstream of the RST2 trapping site ranged from 2,900 to 13,800 , with considerable year-to-year variation across the entire study period (Figure 6.3, Appendix 6.4a). To compare changes between Treatment 1 and 2, we only compare abundance for cohorts that reared entirely under Treatment 1 or 2. Since Treatment 1 was implemented in 1997, we included Treatment 1 smolt estimates from 2000-2008 and Treatment 2 estimates from 20102021( 2009 cohort reared under both Treatment 1 and 2). We used the mainstem Coho abundance estimates for evaluating flow treatment effects. We consider abundance from mainstem habitats a more sensitive measure of the effect of flow treatments than estimates that incorporate abundance from constructed off-channel habitats as well, which are buffered from mainstem flows either by groundwater effects or have independently controlled water intakes.

The mean abundance of mainstem smolts was 6,173 during Treatment 1 and 8,013 during Treatment 2 (Figure 6.4) and did not amount to a statistically significant change in abundance (2tailed t-test, $p=0.07$; Table 6.1). Generally, smolt estimates varied more during Treatment 1 (range: 2,870-11,036) than during Treatment 2 (range: 6,573-10,935; Figure 6.3). This consistency in the year-to-year mainstem smolt yield during Treatment 2 is a potentially important outcome of the flow experiment. Maximum smolt yield was similar during each treatment period but minimum yield was lower and occurred more frequently during Treatment 1 (Figure 6.3). This suggests that freshwater carrying capacity was not increased for all years during Treatment 2 , rather, that it increased primarily for lower abundance years. We would have expected an increase in carrying capacity to result in an upward shift from the Treatment 1 smolt yield or just an increase in maximum yield. An increase in the minimum smolt yield could indicate a more complex relationship with habitat carrying capacity mediated by an additional variable, such as the type of carrying capacity, which may only be influenced by the flow treatment under some conditions. An alternative explanation is that carrying capacity was unchanged and the higher minimum smolt yield was a product of higher adult escapement.

Figure 6.3 Annual Coho smolts yield and $95 \%$ confidence intervals for the 7.5 km study section of the Coquitlam River mainstem as well for individual reaches 2-4. The colours of the bars reflect the flow treatment period that cohorts were reared under: Treatment 1(red), both treatment conditions (blue), Treatment 2 (green).

Table 6.1 Comparison of mean smolt yield, standard deviation (SD) and number of annual estimates ( N ) during Treatment 1 and Treatment 2 in the Coquitlam River including the $p$-values for the two-tailed tests and percent change in mean abundance between Treatment 1 and 2. Only annual estimates for cohorts that reared exclusively under either Treatment 1 or Treatment 2 conditions were included. For Coho, this includes 2000-2008 for Treatment 1 and 2010-2021 for Treatment 2.

| Smolt yield | Treatment 1 |  |  | Treatment 2 |  | $t$ test |  | \% change | Null Hypothesis of no change ( $\mathrm{p}<0.05$ ) |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | Mean | SD | N | Mean | SD | N | p value |  |  |
| Coho (Total) | 12,949 | 2,719 | 8 | 11,651 | 4,242 | 12 | 0.28 | -10\% | do not reject |
| Coho (Mainstem) | 6,173 | 2,954 | 8 | 8,104 | 2,179 | 12 | 0.07 | 31\% | do not reject |
| Coho (Reach 2) | 2,118 | 1,728 | 8 | 3,012 | 726 | 10 | 0.23 | 42\% | do not reject |
| Coho (Reach 3) | 2,541 | 823 | 8 | 3,479 | 757 | 10 | 0.19 | 37\% | do not reject |
| Coho (Reach 4) | 1,844 | 563 | 8 | 1,789 | 822 | 10 | 0.89 | -3\% | do not reject |

## 6. Fish Productivity during Treatment 1 and 2

Figure 6.4 Mean Coho smolt yield and $95 \%$ confidence intervals for Treatment 1 and Treatment 2 for the 7.5 km study section of the Coquitlam River mainstem and in reaches 2-4. Only annual estimates for cohorts that reared exclusively under either Treatment 1 or Treatment 2 conditions were included. For Coho, this includes 2002-2008 for Treatment 1 and 2010-2021 for Treatment 2.

Figure 6.5 Average effect size and $95 \%$ confidence intervals of the change in smolt yield from Treatment 1 to 2 for Coho for the 7.5 km study section of the Coquitlam River mainstem (red) and for individual reaches 2-4 (blue). For Coho, this includes smolt estimates from 2000-2008 for Treatment 1 and 2010-2021 for Treatment 2.

The amount that abundance changed between treatments (effect size) is a more useful measure for evaluating changes in smolt yield than testing merely whether the means are statistically different. The mean increase in mainstem abundance estimates between Treatment 1 and Treatment 2 was $31 \%$, but with broad confidence intervals that span the null hypothesis from no change to a $74 \%$ increase (Figure 6.5). This is an ambiguous result since it includes both a decrease and increase in smolt yield. The mean increase was highest for reach 2 (42\%),
followed by reach $3(37 \%)$ and reach 4 ( $-3 \%$, Figure 6.5 , Table 6.1 ). The high uncertainty for reach 2 is largely a result of the high variability between annual estimates, particularly during Treatment 1 (Figure 6.3).

The assessment of whether the assumption of the Before-After experimental design was satisfied based on the change in abundance in the Coquitlam River compared to 'control' rivers was not updated in this report due to the lack of updated abundance estimates for the 'control' rivers (2000-2018). Results from the comparison in the change in smolt abundance in the Coquitlam River mainstem between Treatment 1 and 2 compared the change in 'control' rivers over a similar period provides no support that the increase smolt production between Treatment 1 and 2 was the result of the flow treatment or that BA comparison was relatively unaffected by other factors. Mean smolt yield in the control streams increased a similar or greater amount as the Coquitlam, depending on whether the Alouette River was included as a control stream or not, (Figure 6.6). This is contrary to the expectation if the BA assumption was satisfied (i.e., larger increase for the Coquitlam than control streams). The reliability of these results depends on how well the control streams reflect the non-treatment factors influencing smolt yield in the Coquitlam River, which we estimate at no higher than moderate. For the Keogh and Sakinaw rivers, which were only moderately correlated with the Coquitlam pre-Treatment 2, it isn't certain that these streams are adequate controls for the Coquitlam. This also applies to the Alouette but with the additional uncertainty about the amount the pre-2008 estimates were biased low. While the Alouette River is possibly the most suitable control stream, based on proximity, watershed similarity and fish assemblage, Cope (2015) concluded that smolt yield estimates for the Alouette River were biased low prior to 2008, when the trapping site was repositioned further upstream to avoid tidal-driven backwatering. This analysis is not intended to replace or supersede smolt yield as the primary metric for evaluating fisheries benefits. It does provide useful context to interpret the likely rise in smolt yield, and raises the possibility that some of the increased yield was due to non-treatment effects.

Coho egg-to-smolt survival remained consistently low (0.03-0.55\%) for the 2002-2020 brood years (Table 6.4b), with the highest values associated with the lowest escapements. These values decreased from Treatment 1 and 2 (mean: $0.3 \%$ and $0.1 \%$, respectively; 2 -tailed t-test $p=0.01$ ). We are cautious about any between-treatment evaluations using adult escapement estimates, which are likely not comparable because of the change in survey methods employed during Treatment 2.

Figure 6.6 Mean percent change in Coho smolt yield and 95\% confidence intervals from Treatment 1 (2000-2008) to Treatment 2 (2010-2018) in mainstem habitats in the Coquitlam River and control streams (Alouette and Keogh rivers, and Sakinaw Creek) with including all streams (Controls) or excluding the Alouette River (Controls_no_Alouette). This includes smolts estimates for cohorts that reared entirely under only Treatment 1 or 2, including 2000-2008 for Treatment 1 and 2010-2018 for Treatment 2. Note that Alouette and Sakinaw data sets did not included all years.

Table 6.2 Comparison of alternative Ricker stock-recruitment model predicting Coho smolt abundance as a function of adult abundance. Mean covariate effect denote the mean proportion of the total effect due to the covariate as well as the direction of the effect. $\mathrm{R}^{2}$ is the proportion of observed variance in $\log$ fry abundance predicted by the model, and $\triangle \mathrm{DIC}$ is the difference in the deviance information criteria for each model relative to the model with the lowest value (the best model). This includes the 2002-2019 brood years. Shaded rows indicate models with high model support ( $\Delta \mathrm{DIC}<2$ ).

6. Fish Productivity during Treatment 1 and 2

The covariate stock-recruitment analysis meant to identify the dominant influences on juvenile production had mixed results depending on whether only Treatment 2 was included or both Treatment periods. For Treatment periods 1 and 2, the only model with high support (Model 9-Stranding: $\Delta \mathrm{DIC}<2$, Table 6.2) and explained $60 \%$ of the variation in smolt abundance. The mean covariate effect of stranding had twice the magnitude of any other covariate and since this it was negative, it had the expected result of decreasing abundance from what would be expected by spawner abundance alone. This was largely due to high stranding levels for three years that also had high spawner abundance (upper left pane, Figure 6.7). The large negative stranding effect for these years resulted in the abundance explained by the stock-recruitment component to shift upwards. The increasing slope of the of the stock-recruitment curve suggests the juvenile carrying capacity had not been reached even at the highest spawner abundance levels, contrasted by the indications of reaching carrying capacity at higher spawner levels with the Base Ricker model (no covariate) by the domed shape of its stock-recruitment curve (Figure 6.8). Model 8, representing the flow treatment effect had low support ( $\Delta \mathrm{DIC}=9.46$ ) and a relatively small covariate effect ( -0.16 ). What is surprising about the relatively high effect of the stranding model is that the covariate uses the number of fish salvaged, which is not a direct measure of mortalities since many are returned to the river alive. If the model does reflect a true effect from standing, this raises the possibility that stranding may largely not be mitigated by salvage.

Figure 6.7 Fit of Ricker adult-to-smolt stock-recruitment covariate model for the Coquitlam River during Treatment 1 and 2 years (2002-2019 brood years) using the number of Coho fry stranded in May-July as the covariate, the model with the highest model support (lowest DIC value). Upper left pane shows the best fit line for the relationship between spawners and smolts, and model fit $\left(\mathrm{R}^{2}\right)$. The lower right pane shows the relative influence of the covariate across years.
6. Fish Productivity during Treatment 1 and 2

Figure 6.8 Fit of the Base Ricker adult-to-smolt stock-recruitment model (no covariates) for the Coquitlam River during Treatment 1 and 2 years (2002-2019 brood years).

Since adult escapement estimates for Treatment 1 are likely biased, we repeated this analysis only including brood years during Treatment 2. For Treatment 2 years, the covariate model including the mean flow during August was the only model with high support ( $\triangle \mathrm{DIC}<2$, Table $6.3)$ and explained the most variance $\left(\mathrm{R}^{2}=0.89\right)$. The model including the number of stranded fry shifted to the second ranked model, and the only one with moderate support ( $\Delta \mathrm{DIC}=5.2, \mathrm{R}^{2}$ $=0.65$ ).

Table 6.3 Comparison of alternative Ricker stock-recruitment model predicting Coho smolt abundance as a function of adult abundance. Mean covariate effect denote the mean proportion of the total effect due to the covariate as well as the direction of the effect. $\mathrm{R}^{2}$ is the proportion of observed variance in $\log$ fry abundance predicted by the model, and $\triangle$ DIC is the difference in the deviance information criteria for each model relative to the model with the lowest value (the best model). This includes the 2008-2019 brood years. Shaded rows indicate models with high model support ( $\Delta \mathrm{DIC}<2$ ).

### 6.2.3 Mainstem fall fry abundance

The abundance of Coho fry from the snorkel survey based standing stock assessment has varied from a low of 18,000 in 2007 to 91,000 in 2011 (Figure 4.3). Mean fry abundance increased
6. Fish Productivity during Treatment 1 and 2
$83 \%$ from Treatment 1 to Treatment 2 (2-tailed $t$-test: $p=0.08$, Figure 6.9). However, the change in fry abundance between the treatments could be explained by both the change in flow treatment as well as the change in adult escapements. Adult Coho escapement during the three years of Treatment 1 was far lower than during the years of Treatment 2 (Treatment 1: 940-2400 adults; Treatment 2: 3,200-13,000). Mean estimated egg-to-fall fry survival during Treatment 1 and 2 was $1.3 \%$ and $0.8 \%$ respectively, though they were not significantly different ( 2 -tailed t -test, $\mathrm{p}=$ 0.39 ). All three years of Treatment 1 survival estimates correspond to very low escapements.

Figure 6.9 Mean Coho fall fry abundance and $95 \%$ confidence intervals during Treatment 1 (2006-2008) and Treatment 2 (2009-2021) for the 7.5 km study section of the Coquitlam River mainstem.

There was high support for Ricker spawner to fall fry stock-recruitment models that included the covariate representing the proportion of days in August with flows greater than $5.4 \mathrm{~m}^{3} / \mathrm{s}$ or the number of fry stranded during May-July ( $\Delta \mathrm{DIC}<2$, Table 6.4). While the covariate Proportion Aug $>5.4 \mathrm{cms}$ explained more of the variance in fall fry abundance than Stranded ( $\mathrm{R}^{2}$ : 0.76 vs 0.67 , respectively), it did so due to its ability to explain the higher than expected fry abundance given the near record low spawner abundance of the 2008 brood year (upper left pane, Figure 6.10). This is evident from the large vertical offset (dashed lines) relative to the predicted fry abundance due to adults alone. The high influence of a single data point increases the uncertainty of the model, as reflected in the high maximum covariate effect size (red line, lower right pane, Figure 6.10) relative to the mean effect (black line). Using the number stranded during the May-July as the covariate, there were a several years where with a relatively large covariate effect (upper left pane, Figure 6.11). The models predicted fall fry abundance increased with the number of days in August with flows greater than $5.4 \mathrm{~m}^{3} / \mathrm{s}$ and decreased as the number of fry stranded increased. The model with Treatment as the covariate had moderate support ( $\Delta \mathrm{DIC}=3.07$ ) and explained $59 \%$ of the variance in fall abundance $\left(\mathrm{R}^{2}=0.59\right)$. However, the negative value of the covariate effect indicated that the model best fit the data with

Treatment 2 decreasing abundance from what would be predicted by spawner abundance. While it isn't clear which factor was driving fall fry production, there is only moderate support that it was flow treatment.

Table 6.4 Comparison of alternative Ricker stock-recruitment model predicting Coho fall fry abundance as a function of adult spawner abundance. Mean covariate effect denote the mean proportion of the total effect due to the covariate as well as the direction of the effect. $R^{2}$ is the proportion of observed variance in $\log$ fry abundance predicted by the model, and $\triangle$ DIC is the difference in the deviance information criteria for each model relative to the model with the lowest value (the best model). This includes the 2005-2020 brood years. Shaded rows indicate models with high model support ( $\Delta \mathrm{DIC}<2$ ).

Figure 6.10 Fit of Coho adult-to-fall fry Ricker covariate model using number of the proportion of days in August with flows greater than $5.4 \mathrm{~m}^{3} / \mathrm{s}$ as the covariate for the Coquitlam River during Treatment 1 and 2 years (2005-2020 brood years). The upper-left panel shows the best fit line for the relationship between spawners and smolts, and model fit $\left(\mathrm{R}^{2}\right)$. This model shifts the stock-recruitment curve each year based on the number of stranded Coho fry salvaged following ramping events March-September. The vertical dashed lines show the covariate offset due to the covariate.

Figure 6.11 Fit of Coho adult-to-fall fry Ricker covariate model using number of fish stranded as the covariate for the Coquitlam River during Treatment 1 and 2 years (2005-2020 brood years). The upper-left panel shows the best fit line for the relationship between spawners and smolts, and model fit $\left(\mathrm{R}^{2}\right)$. This model shifts the stockrecruitment curve each year based on the number of stranded Coho fry salvaged following ramping events MarchSeptember. The vertical dashed lines show the covariate offset due to the covariate.

### 6.3 Steelhead

### 6.3.1 Off-channel smolt abundance

Steelhead smolt yield from off-channel habitats represents only a small proportion of the total yield ( $0.3 \%-9 \%$ of total annual yield). Thus, off-channel smolt production is not used to evaluate the fisheries benefits of Treatment 1 and 2 flow regimes.

### 6.3.2 Mainstem smolt abundance

During 2000-2021 the estimated number of Steelhead smolts outmigrating from the 7.5 km study section of the Coquitlam River mainstem upstream of the RST2 trapping site ranged from 2,200 to 5,500 (Figure 6.12). Mean smolt yields for cohorts that reared exclusively under Treatment 1 or Treatment 2 were statistically different ( 3,701 smolts and 4,778 smolts; respectively; 2 -tailed t -test $p=0.02$, Table 6.5 ). This included smolt estimates from the years 2002-2008 for Treatment 1 and years 2012-2021 for Treatment 2 . This was driven primarily by the increase in smolt abundance in reach 4. Mean abundance increased more than two-fold in reach 4 from Treatment 1 to Treatment 2 (mean: 925 and 1,938 smolts, respectively; t-test, $p<0.01$; Table 6.5, Figure 6.13), whereas yields from reaches 2 and 3 were similar during both treatment periods. This result is consistent with the hypothesis that the relatively confined
6. Fish Productivity during Treatment 1 and 2
channel in reach 4 combined with the higher Treatment 2 base flows would produce a higher energy flow environment, which would be more favorable to juvenile Steelhead.

Table 6.5 Comparison of mean smolt yield, standard deviation (SD) and number of annual estimates (N) during Treatment 1 and Treatment 2 in the Coquitlam River including the p-values for the two-tailed $t$ tests and percent change in mean abundance between from Treatment 1 to 2. Only annual estimates for cohorts that reared exclusively under either Treatment 1 or Treatment 2 conditions were included. For Steelhead, this includes 20002008 for Treatment 1 and 2012-2020 for Treatment 2.

| Smolt yield | Treatment 1 |  |  | Treatment 2 |  |  | t test |  | Null Hypothesis of no change ( $\mathrm{p}<0.05$ ) |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | Mean | SD | N | Mean | SD | N | p value | \% change |  |
| Steelhead (Total) | 3,799 | 993 | 7 | 4,829 | 257 | 10 | 0.03 | 27\% | do not reject |
| Steelhead (Mainstem) | 3,701 | 978 | 7 | 4,778 | 240 | 10 | 0.02 | 29\% | reject |
| Steelhead (Reach 2) | 1,827 | 524 | 7 | 1,716 | 643 | 6 | 0.89 | -6\% | do not reject |
| Steelhead (Reach 3) | 944 | 464 | 7 | 868 | 590 | 6 | 0.80 | -8\% | do not reject |
| Steelhead (Reach 4) | 925 | 301 | 7 | 1,938 | 571 | 9 | 0.00 | 110\% | reject |

Figure 6.12 Annual Steelhead smolts yield and $95 \%$ confidence intervals for the 7.5 km study section of the Coquitlam River mainstem as well for individual reaches 2-4. The colours of the bars reflect the flow treatment period that cohorts were reared under: Treatment 1(red), both treatment conditions (blue), Treatment 2 (green).

Figure 6.13 Mean Steelhead smolt yield and 95\% confidence intervals for Treatment 1 and Treatment 2 for the 7.5 km study section of the Coquitlam River mainstem and in reaches 2-4. Only annual estimates for cohorts that reared exclusively under either Treatment 1 or Treatment 2 conditions were included. This includes 2002-2008 for Treatment 1 and 2012-2020 for Treatment 2.

The mean increase in mainstem abundance from Treatment 1 to 2 was $29 \%$ (Figure 6.14). For reaches 2 and 3, there was no clear indication that abundance changed from Treatment 1 to 2. The mean change was above $100 \%$ (or a doubling in abundance) in reach 4 but was also highly uncertain. The high uncertainty for individual reaches isn't surprising given the relatively high variability within each treatment period compared to estimates for the entire mainstem (Figure 6.12). As with Coho, to interpret this change as a response to the Treatment 2, we must assume other factors, such as adult escapement, had a relatively small influence on smolt yield during the flow experiment.

Figure 6.14 Average effect size and $95 \%$ confidence intervals of the change in smolt yield from Treatment 1 to 2 for Coho and Steelhead for the 7.5 km study section of the Coquitlam River mainstem (red) and for individual reaches 2-4 (blue). This includes 2002-2008 for Treatment 1 and 2012-2020 for Treatment 2.

Using the same method as for Coho, we compared the relative increase in smolt yield in the Coquitlam River to comparable watersheds to test that region wide influences were minor compared to flow treatment effects, a key assumption of the before-after experimental design. Appendix 6.8 lists the annual smolt yield for the two Coastal BC streams considered for use as controls. We were limited to only the Alouette River for this comparison since it was the only stream with adequately similar smolt yield trends for cohorts that reared prior to Treatment 2 (correlation coefficient: Keogh $\mathrm{R}<0.01$, Alouette $\mathrm{R}=0.52$, Appendix 6.9 ). For this analysis, we only included commonly monitored years during Treatment 1 (2002-2008) and Treatment 2 (2012-2018). The mean percent increase in smolt yield between treatment periods was higher for the Alouette ( $74 \%$ ) than for the Coquitlam ( $30 \%$ ), with considerable overlap in their confidence intervals (Figure 6.15).

This analysis depends on the credibility of the Alouette River smolt data as an index of region wide productivity. As mentioned for Coho, the estimates for the Alouette prior to 2008 may be biased low due to backwatering at the trapping site and shorter monitoring period (Cope 2015). If the bias was large, what we are considering as a non-treatment effects on productivity would instead be an artifact of the changes in monitoring. Support for using the Alouette River relies on is its close proximity, consistent flow regulation, and similar geomorphology, fish assemblage and abundance trends to the Coquitlam. On this basis, it is a useful control. Its weakness is due to the uncertainty in the amount pre-2008 smolt estimates are biased. The possibilities to resolve this rely on accessing additional data from other coastal BC watersheds and further investigating the degree that the Alouette smolt estimates are biased. Given this uncertainty and that no other comparison streams are included, it is difficult to determine whether this analysis is sufficiently reliable to consider in the assessment of the fisheries benefits.

Figure 6.15 Average percent change in Steelhead smolt yield and $95 \%$ confidence intervals from Treatment 1 (2000-2008) to Treatment 2 (2010-2018) in mainstem habitats in the Coquitlam River and Alouette River. This
6. Fish Productivity during Treatment 1 and 2
includes 2002-2008 during Treatment 1 and 2012-2018 during Treatment 2. Note that for the Alouette River, estimates were only available during Treatment 2 up to 2014.

On average, fork lengths of Steelhead smolts were $6-7 \mathrm{~mm}$ less during Treatment 1 than Treatment 2 in reach 4 , and reaches 2 and 3 combined ( 2 -tailed $t$-test $p<0.01$ for both). Age- $1+$ spring migrant parr in reach 4 were on average 10 mm larger than those in reaches 2 and 3 ( t -test $\mathrm{p}=0.01$ ).

Steelhead spawner densities appeared to be well above levels thought to be required for full seeding of juvenile habitat for during 2005-2021. During 2005-2021, Steelhead spawner densities in the Coquitlam River ranged from 24 to 80 fish $/ \mathrm{km}$ (mean: 38 fish $/ \mathrm{km}$ ). This translates to 39,000-149,000 eggs/km deposited in the Coquitlam River during 2005-2020 (Table 3.2). In the Keogh River 13,300 eggs/km was estimated as the minimum required to achieve optimal smolt yield (derived from Ward and Slaney 1993). Moreover, the horizontal spread of data points in the Ricker stock-recruitment relationship for the 2005-2018 brood years suggests the variation in adult abundance had a relatively small effect on smolt abundance (Figure 6.16).

These results suggest that the juvenile carrying capacity of the Coquitlam River, as opposed to adult escapement, had a major influence on Steelhead smolt yield for these adult brood years. With the 2005 brood as the only one to rear entirely under Treatment 1 conditions and all others reared under both treatments or Treatment 2, adult-to-smolt survival has little use for directly assessing the effect of the flow treatment. Instead, we used a stock-recruitment covariate model for the adult-to-fall fry and fall fry-to-fall age-1 parr life stages to address this question.

Figure 6.16 Fit of Ricker stock-recruitment model to adult-to-smolt abundance for the Coquitlam River for the 2005-2018 brood years.

### 6.3.3 Mainstem fry and parr abundance

Based on snorkeling surveys alone, average fall abundance of fry was 70,963 for Treatment 1 and 41,959 for Treatment 2, though this difference was not significant ( t -test $p=0.08$, Figure 6.17). The higher mean and lower precision for Treatment 1 is largely due to 2006, when high escapement resulted in over two-folder higher fry abundance than any other years during the
study (Figure 6.18). Without 2006, the mean fry abundance during Treatment 1 of 37,300 is far more similar to Treatment 2 ( 41,959 fry). However, relying on only two Treatment 2 sampling years is too vulnerable to bias to represent fry abundance across all of Treatment 1. The 2006 escapement was over $50 \%$ higher than the next highest year during the entire study (Table 3.2). Age $1+$ parr abundance was similar between Treatment 1 and 2 (age $1+$ parr 8,812 and 8,404; respectively; t -test $p=0.78$ ). Age $2+$ parr were only half as abundant during Treatment 1 than during Treatment 2 (age $2+$ parr 1,691 and 3,010; respectively; t-test $p<0.01$ ). However, the abundance of age $2+$ parr is the product of surviving to that age as well as not smolting during the prior spring. Coquitlam Steelhead smolt after their $2^{\text {nd }}$ or $3^{\text {rd }}$ winter, which is size and growth dependent (Kendall et al 2015). The increase in age $2+$ parr could be a result of increased survival during their $2^{\text {nd }}$ winter, increased proportion of age 3 smolts and movement of downstream parr into the study area.

Figure 6.17 Average abundance and $95 \%$ confidence limits for Steelhead fry, age-1 parr and age-2 parr during Treatment 1 and 2 in reaches 2-4 of the Coquitlam River. The start of Treatment 2 for Steelhead fry, age-1 parr and age-2 parr is 2009, 2010 and 2011; respectively.

Figure 6.18 Estimates of juvenile standing stock, and $95 \%$ confidence intervals by species and age class in Coquitlam River during 2006-2021. Estimates were derived from night snorkeling counts with the exception of 2011 Steelhead (0+), which were based on electrofishing. Bar colour indicates cohorts that were reared entirely under Treatment 1 flows (red), Treatment 2 (green) or both (blue).

Steelhead egg-to-fry survival averaged $7.7 \%$ during Treatment 1 and $6.4 \%$ during Treatment 2 and were not significantly different (t-test $p=0.13$, Appendix 6.4b). This is similar to the Keogh River (mean: 6.5\%, Ward and Slaney 1993) but far lower than the Cheakamus (mean: $22.8 \%$, Korman and Schick 2018). Fall fry-to-fall age-1+ parr survival averaged were also similar to Treatment 1 and $2(20 \%$ and $22 \%$, respectively; t-test $p=0.70$; Appendix 6.4b). Age$1+$ parr-to-smolt survival were also similar during Treatment 1 and 2 ( $55 \%$ and $57 \%$, respectively; t-test $p=0.87$; Appendix 6.4 b ). This is comparable to parr-to-smolt survival for Steelhead in the Keogh River (48.8\%; Tautz et al. 1992).

The Ricker stock-recruitment models using adult escapement with and without a covariate were all poor predictors of fall fry abundance $\left(\mathrm{R}^{2}<0.23\right.$, Table 6.6$)$. While the Base Ricker and the model using June mean discharge as the covariate were the only models with high support ( $\Delta \mathrm{DIC}<2$ ), they had limited usefulness for explaining fry abundance given they explained only $6 \%$ and $23 \%$ of fall fry abundance $\left(\mathrm{R}^{2}=0.06\right.$ and 0.23 , respectively). To test whether the poor fit was a product of the 2006 brood year, which had both the highest spawner escapement and fry abundance (upper left pane, Figure 6.19), we excluded this year in a repeat analysis. However,

## 6. Fish Productivity during Treatment 1 and 2

model ranking remained unchanged and no model explained over $40 \%$ of the variance in fall abundance. The June mean flow model and Base Ricker model remained the only with high support. There was no improvement in fit for the June Mean covariate ( $\mathrm{R}^{2}<0.24$ ) but it did improve for the Base Ricker model $\left(R^{2}=0.36\right)$. With models explaining only a low amount of variation in fall fry abundance, it provides little information about the primary factors influencing juvenile production during this early life-stage.

Table 6.6 Comparison of alternative Ricker covariate stock-recruitment model predicting Steelhead fall fry abundance as a function of adult abundance. This includes the 2006-2021 brood years. Shaded rows indicate models with high support ( $\Delta \mathrm{DIC}<2$ ).

Figure 6.19 Fit of Ricker adult-to-fall fry covariate model to adult-to-fall fry using June mean discharge as the covariate for the Coquitlam River during Treatment 1 and 2 years (2006-2020 brood years). The upper-left panel shows the best fit line for the relationship between spawners and smolts, and model fit $\left(\mathrm{R}^{2}\right)$. This model shifts the stock-recruitment curve each year based on mean June discharge at the Port Coquitlam gauge. The vertical dashed lines show the offset due to the covariate.

For the fall fry to fall age-1 parr life stage, the Ricker covariate stock-recruitment analysis provided unclear information about which the primary influences on productivity during this lifestage. The analysis indicated three models had high support ( $\Delta \mathrm{DIC}<2$, Table 6.7) and explained a similar amount of abundance $\left(R^{2}=0.65-0.70\right.$, Figures 6.20-6.22). The models included one of three covariates along with fall fry abundance: the number of days with flows greater than 5.4 $\mathrm{m} 3 / \mathrm{s}$ during September, flow treatment period, and the mean flow during the spring (April-May). Contrary to expectations, the flow treatment model predicted higher parr abundance for Treatment 1 broods than Treatment 2 (negative covariate effect, Table 6.7). However, with only two Treatment 1 years the effect could be due to coincidence. For all models, covariates had effects were small ( $\mathrm{R}^{2}<0.14$ ), indicating a low influence of the covariates compared to the influence of fall fry abundance.

Table 6.7 Comparison of alternative Ricker covariate stock-recruitment model predicting Steelhead fall age-1 parr abundance as a function of fall fry. This includes the 2006-2020 brood years. Shaded rows indicate models with high support ( $\Delta \mathrm{DIC}<2$ ).

6. Fish Productivity during Treatment 1 and 2

Figure 6.20 Fit of Ricker fall fry-to-fall age-1 parr covariate model using days during September with flows greater than $5.4 \mathrm{~m}^{3} / \mathrm{s}$ as the covariate for the Coquitlam River during Treatment 1 and 2 years (2006-2020 brood years). The upper-left panel shows the best fit line for the relationship between spawners and smolts, and model fit $\left(\mathrm{R}^{2}\right)$. This model shifts the stock-recruitment curve each year based on whether rearing occurred under Treatment 1 flows (2006-2007 brood years) or Treatment 2 (2008-2020 brood years). The vertical dashed lines show the offset due to the covariate.

Figure 6.21 Fit of Ricker fall fry-to-fall age-1 parr covariate model using flow treatment period (1or 2 ) as the covariate for the Coquitlam River during Treatment 1 and 2 years (2006-2020 brood years). The upper-left panel shows the best fit line for the relationship between spawners and smolts, and model fit $\left(\mathrm{R}^{2}\right)$. This model shifts the stock-recruitment curve each year based the mean April-May discharge. The vertical dashed lines show the offset due to the covariate.

## 6. Fish Productivity during Treatment 1 and 2

Figure 6.22 Fit of Ricker fall fry-to-fall age-1 parr covariate model using the mean discharge during April-May (Mean Spring) as the covariate for the Coquitlam River during Treatment 1 and 2 years (2006-2020 brood years). The upper-left panel shows the best fit line for the relationship between spawners and smolts, and model fit ( $\mathrm{R}^{2}$ ). This model shifts the stock-recruitment curve each year based the mean April-May discharge. The vertical dashed lines show the offset due to the covariate.

### 6.4 Chum

### 6.4.1 River-wide abundance and survival

Similar to that for Coho and Pink, escapement and egg-to-fry survival estimates for Chum should be considered preliminary and will likely change as adult salmon observer efficiency and survey life data are collected in future years. Adult returns of Chum salmon to Coquitlam River (including Reach 1) have ranged from 12,000-78,000 (Appendix 6.4a), while fry production upstream of RST2 has ranged from 0.8 to 12.7 million. During Treatment 1 (2002-2007 brood years) Chum egg-to-smolt survival ranged from $3.7 \%$ to $14.1 \%$ and $18.1 \%$ to $40.0 \%$ during Treatment 2 (2008-2020 brood years, Appendix 6.4b). Mean survival increased from $10.2 \%$ for Treatment 1 to $22.7 \%$ for Treatment 2 (t-test $p=0.01$, Figure 6.23).

Figure 6.23 Mean egg-to-fry survival and $95 \%$ confidence intervals for Chum Salmon broods reared under Treatment 1 (2002-2007) and Treatment 2 (2008-2020) in the Coquitlam River study area.

Bradford (1995) reported an average egg-to-smolt survival rate of $6.7 \% ~( \pm 1$ standard deviation $=$ $3.3 \%-13.5 \%$ ) for Chum populations in nine Pacific Northwest streams. The Chum egg-to-fry survival estimates for the 2005, 2008, 2010, 2013 and 2014 brood years in the Coquitlam River exceeds published values for this species, and these, and possibly all, may be biased high. The most plausible source of this bias would be an underestimate of Chum escapement (see Section 2.2) as opposed to an overestimate of Chum fry. The study design for estimating fry yield is robust: sampling was nearly daily over the entire outmigration period; it accounts for changes in capture efficiency over the outmigration period by stratifying into 8-10 distinct periods; and used a large number of marked fish (800-2000) to estimate capture efficiency for each strata. Escapement estimates depend on estimating both observer efficiency and survey life. Even with considerable effort, these two parameters remain highly uncertain. For instance, there is only a weak relationship between an observer's guess of their efficiency and the markrecapture based estimate of their efficiency $\left(\mathrm{R}^{2}=0.38\right)$. This level of uncertainty remains too large for the escapement model to generate both credible escapement estimates and precision estimates (see section 2.2.3). Given the weaknesses of adult salmon escapement estimates we view them as an index of abundance rather than accurate measures of escapement. As well, considering that our survival estimates could be biased and unknown (but likely high) uncertainty of adult escapement, we encourage a conservative approach to interpreting any statistical tests using this metrics.

There was strong support of a linear escapement-to-fry relationship during Treatment 2 $\left(R^{2}=0.71\right.$, Figure 6.24$)$ but only moderate support of one during Treatment $1\left(R^{2}=0.36\right)$. The lower fit during Treatment 1 was largely the result of 2005, when fry production was considerably higher than expected. If this was considered an outlier and excluded, there would be a high level of support for a linear relationship during Treatment $\left(R^{2}=0.78\right)$. A linear relationship confirms that with changes in egg-to-fry survival or fry- per-adult are more appropriate methods for evaluating the fisheries benefits of flow treatments than juvenile production alone.

Figure 6.24 Escapement-to-fry stock-recruitment relationships of Chum Salmon during flow Treatment 1 (20022008) and Treatment 2 (2009-2019) for the Coquitlam River study area. The best-fit lines intercept the x and y axis at 0 as is typical of stock-recruitment relationships. $\mathrm{R}^{2}$ values reflect the fit of stock-recruitment.

Based on an analysis of covariance (ANCOVA), to evaluate the Chum fry-per-adult relationship for Treatment 1 and 2 using the package STATS in R (R Development Core Team 2009). The test whether flow treatment had a significant effect on recruitment, we evaluated whether the y-intercepts differed for the $\ln$ (fry/adult) ~ adult relationship between Treatment 1 and 2 (Figure 6.25). Using $\ln$ (fry/adult) instead of fry in the analysis reduces the violation of the assumption that linear stock-recruitment intercept at 0 adults and 0 juveniles. In effect, it becomes a test of whether adult-to-fry survival changes by flow treatment. Appendix 6.11 provides outputs of this analysis for Chum 2003-2016 and 2018-2020 brood years. The results are consistent with the comparison of egg-to-fry survival above. The significant values for Treatment and intercept (both $\mathrm{p}<0.02$ ) support hypothesis that fry-per-adult recruitment differed between Treatment 1 and 2 . However, as previously discussed, unaccounted for bias and uncertainty in the adult escapement data also impacts this test. Thus, results should be interpreted with this in mind.

Figure 6.25 Adult-to-ln(fry/adult) stock-recruitment relationships of Chum during flow Treatment 1 (2002-2008) and Treatment $2(2009-2020)$ from 7.5 km of the Coquitlam River used for the ANCOVA tests as to whether flow treatment had a significant effect of productivity.

## 6. Fish Productivity during Treatment 1 and 2

As for Coho and Steelhead, an effective way to distinguish between the effects of the flow treatment and other factors influencing freshwater conditions is by comparison with other watersheds. Chum escapement and juvenile abundance has been monitored in the Alouette and Cheakamus River. During 2002-2014, both Chum escapement and fry yield in the Coquitlam River are only minimally to moderately correlated with that in the Alouette River (escapement: $R=0.55$, fry yield: $\mathrm{R}=0.03$; Figure $6.26 a$; Cope 2015), which reduces the viability of using the Alouette River as a control of region-wide factors influencing Chum productivity. With the end of monitoring on the Alouette in 2014, these values will remain unchanged. Chum escapement and fry yield were strongly and moderately correlated with the Cheakamus River ( $\mathrm{R}=0.79$ and $\mathrm{R}=0.57$; Figure 6.26 b ) suggesting it has a moderate use as a comparison when evaluating whether changes in productivity in the Coquitlam are the result of flow treatments or region wide factors. However, a drawback in using the Cheakamus is that the switch in 2016 between IFA and WUP flow regimes occurred at a similar time as the change between Treatment 1 and 2 on the Coquitlam. Even with a potential increase in productivity for the Cheakamus under WUP flows, there was a relative increase in fry abundance 2008 onwards in the Coquitlam. While this is possibly an effect of increased escapement, if could also be due to the transition to Treatment 2.

## Year

Figure 6.26a Annual escapement and smolt yield in the Coquitlam River study area versus that in the Alouette River during 2002-2014. Values for the Coquitlam are given on the right-hand axis, and values for the Alouette are given on the left-hand axis.
6. Fish Productivity during Treatment 1 and 2

Figure 6.26b Annual escapement, fry and smolt yield in the Coquitlam River versus that in the Cheakamus River during 2002-2017. Values for the Coquitlam are given on the right-hand axis, and values for the Cheakamus are given on the left-hand axis.

No model explained any more than $44 \%$ of the variance in egg-to-fry survival $\left(\mathrm{R}^{2}<0.44\right.$, Table 6.8). There were six models with high support ( $\Delta \mathrm{AICc}_{\mathrm{c}}<2$ ), with Flow Treatment included in four these. The model representing flow treatment and the number of day above $70 \mathrm{~m}^{3} / \mathrm{s}$ during October to February (Model 8) explained the most variance in egg-to-fry survival ( $\mathrm{R}^{2}=$ 0.44 ), though this was only slightly more than other models that included flow treatment and an additional variable $\left(\mathrm{R}^{2}=0.35-0.41\right)$. While this suggests flow treatment is an important influence on survival - similar to the ANCOVA analysis - it is relatively uninformative about the additional influences on survival.
6. Fish Productivity during Treatment 1 and 2

Table 6.8 Model performance of Chum egg-to-fry survival for 2002-2020 brood years by each of the explanatory variables evaluated using, linear ( $\mathrm{r}^{2}$ ), Akaike information criterion (AIC), and the distance from the lowest AIC value ( $\triangle$ AIC). AIC include the penalty for the number of parameters at each sample size. Shading marks the $\operatorname{model}(\mathrm{s})$ with the most support based on $\triangle \mathrm{AICc}$.

Chum

| Model \# | Response variable | Explanatory Variable | $\mathrm{R}^{2}$ | AICc | $\Delta$ AIC |
| :---: | :---: | :---: | :---: | :---: | :---: |

6. Fish Productivity during Treatment 1 and 2

### 6.5 Pink

The section on Pink Salmon productivity is unchanged from the 2020 report since Pink this reporting year was an 'off year' for south coast populations, and thus, no additional juvenile or adult abundance estimates were collected this year. Estimated adult Pink salmon returns to Coquitlam River ranged from 2,900-34,280 adults, with significantly increasing abundance starting in 2009 (Appendix 6.4a). Fry production upstream of RST2 ranged from 148,0006,030,000 (Figure 6.27, Appendix 6.4a), with substantial increases since 2008. The egg-to-fry survival for 2003-2009 Pink broods ( $4.9 \%-10.1 \%$, Appendix 6.4 b ) was comparable to the range reported for Pink populations in 18 other streams (mean: $7.4 \% ; \pm 1$ standard deviation: $3.2 \%-17.0 \%$; Bradford 1995). However, the 2011, 2013 and 2015 brood egg-to-fry survival far exceeded this range (range: $27 \%-48 \%$ ), which signals they could be non-credible or at least, biased high. An unrealistically high value would occur if escapement was biased low or if fry production was biased high. There were no indications of high bias in the escapement or fry estimates for these years, making it difficult to isolate the cause of the high survival rate. However, we have generally lower confidence in escapement estimates considering they depend heavily on assumptions about observer efficiency, survey life and fecundity (see section 2.2 on how this relates to bias and precision). We will gain a better understanding of the accuracy and precision of Pink escapement estimates if the escapement model is provided with sufficient observer efficiency and survey life information.

## Pink fry

Figure 6.27 Estimated abundance of Pink fry outmigrating for the 7.5 km study section of the Coquitlam River. Pink return to south coast rivers on odd years and thus, outmigrate during the spring of even years.

There was weak support for a linear escapement-to-fry stock-recruitment relationship during Treatment $1\left(\mathrm{R}^{2}=0.36\right)$ and strong support for one during Treatment $2\left(\mathrm{R}^{2}=0.81\right.$, Figure 6.28). However, the fit improved when both treatment periods were included ( $R^{2}=0.87$ ), providing some support that the stock-recruitment relationship was similar during Treatment 1 and 2. The good fit of the single linear stock-recruitment relationship over a wide range of
7. Fish Productivity during Treatment 1 and 2
escapements suggests that fry abundance was minimally effected by the availability of spawning habitat. Given that all high escapement years were during Treatment 2 , this provides no information as to whether high escapement under Treatment 1 flows would have resulted in a similar increase in fry abundance. It is still an important finding that freshwater carrying capacity was exceeded under Treatment 2 with adult escapement as high as 25,000 fish, but there is no information to indicate the same would not have occurred under Treatment 1 conditions.

Figure 6.28 Escapement-to-fry stock-recruitment relationships of Pink Salmon during flow Treatment 1 (20022008) and Treatment 2 (2009-2019) from 7.5 km of the Coquitlam River. The best-fit lines intercept the x and y axis at 0 as is typical of stock-recruitment relationships. $\mathrm{R}^{2}$ values reflect the fit of stock-recruitment relationship, with the value at the upper end of the Treatment 2 trend line representing the Treatment 2 fit, and value lower in the figure representing the Treatment 1 fit.

The large effect of adult escapement and lack of a clear indication of flow treatment effect was also found when comparing only years with low escapement. With the low escapement in 2009 and 2019 providing two years with low escapement under Treatment 2, it is now possible to compare egg-to-fry survival under similar escapement levels between Treatment 1 and 2. With these years combined, the fit of a linear stock-recruitment relationship also very high $\left(\mathrm{R}^{2}=\right.$ 0.90). Average egg-to-fry survival was $8.1 \%$ for Treatment 1 and $11.4 \%$ for Treatment 2 with broadly overlapping confidence intervals, indicting they are not significantly different (Figure 6.29).

While our ability to distinguish treatment effects from region-wide abundance trends remains low, results to date strongly suggest that adult escapement is the dominant driver of juvenile production in the Coquitlam River across both treatment periods. Given the lack of a reliable control stream, an alternative approach for distinguishing flow effect from the effects of escapement is to either return to Treatment 1 flow conditions or a switch to a third flow treatment. This would apply to the other three target species as well.
7. Fish Productivity during Treatment 1 and 2

Figure 6.29 Mean egg-to-fry survival for Pink Salmon in the Coquitlam River during Treatment 1 (2003-2007 brood years) and Treatment 2 (2009 and 2019 brood years). The 2011-2017 brood years with escapement above 10,000 were excluded.

Pink salmon were successfully reintroduced to the Coquitlam River in 1995 following their extirpation in the 1960's. Increased minimum flows in Coquitlam River beginning in 1997 likely improved migration and spawning conditions for Pinks. There is some indication that larger dam releases under Treatment 2 have further improved access to spawning habitats for Pink salmon (Macnair 2010b) and may account for the lack of density dependent interactions under higher escapements during this period.
7. Fish Productivity during Treatment 1 and 2

## 7 Conclusions

Study results suggest that the production of juvenile Coho, Chum and Pink Salmon as well as Steelhead have been higher in the Coquitlam River study area during Treatment 2 compared with Treatment 1, but only statistically higher for Steelhead and Chum. For smolts reared in the Coquitlam River mainstem, the mean increased by $31 \%$ for Coho and $29 \%$ for Steelhead. For Chum fry, this reflects a near doubling of the egg-fry productivity. For Pink fry, it is unclear whether egg-fry productivity increased during Treatment 2 , however, there is no indication that spawning habitat limited Pink productivity at high escapement levels during Treatment 2.

We are less certain about whether the increases were a product of the Treatment 2 flows or other factors, such as higher adult escapement or regional environmental changes. If the assumption is correct that these differences were primarily the result of the flow treatment, these results support a conclusion that Treatment 2 flows caused increased freshwater productivity for some species compared to Treatment 1. However, support for this assumption varies by species and is generally uncertain at this point. For Coho, the moderate effect of adult escapement on smolt abundance and the rise in smolt yield in other watersheds raises the possibility that the increase was more the result higher escapement rather than from the flow treatment. There is some indication that the level of stranding due to the June rampdowns during Treatment 2 reduced survival for both adult-to-fall fry and adult-to-smolt life stages. Adult escapement also appears to explain the majority of the variation in Steelhead smolt abundance. However, there was no clear indication that month and season specific flow metrics, or that flow treatment had a substantive effect on either adult-to-fall fry survival or fall fry-to-fall age-1 parr survival. For Chum, results to date suggest that flow treatment period was a significant factor affecting adult spawner-to-fry survival and that mean egg-to-fry survival increased from $10 \%$ to $22 \%$ from Treatment 1 to Treatment 2. For Pink, it is adult abundance alone that explains the $80-90 \%$ of the juvenile abundance during Treatment 1 and 2. The number of abundance estimates is insufficient to reliably compare the influence of multiple factors.

## Current answers to the primary management question:

What are the fisheries benefits associated with each of the proposed test flows evaluated over the review period?

Coho - Mean smolt yield likely increased from Treatment 1 to Treatment 2 (mean increase $31 \%$ ). Maximum smolt capacity was relatively unchanged between treatments but there were a higher number of years with abundance near the maximum carrying capacity during Treatment 2. It remains unclear at this time whether the increased productivity was the result of the Treatment 2, but there is support that adult escapement has a large effect.
Steelhead - Mean smolt yield very likely increased from Treatment 1 to Treatment 2 (mean increase $29 \%$ ). Maximum smolt capacity was relatively unchanged between treatments but there were a higher number of years with abundance near the maximum carrying capacity during Treatment 2. It remains unclear at this time whether the increased productivity was the result of the Treatment 2. There is support that adult escapement had a large effect on smolt productivity.

## 7. Conclusions

There was no clear indication of the effect of flow treatment or other seasonal flow metrics on adult-to-fall fry survival or fall fry-to-fall age-1 parr survival.
Chum - Egg-fry recruitment increased significantly from Treatment 1 to Treatment 2, even when accounting for the number of adult spawners. Beyond the influence of flow treatment and adult escapement, the influence of season specific flow metrics remains uncertain.
Pink - Egg-fry recruitment possibly increased from Treatment 1 to Treatment 2 but this may be a product of the up to 10 -fold higher spawner abundance during Treatment 2 . While there was no clear effect of flow treatment on productivity, there was no indication that juvenile carrying capacity was reached during Treatment 2. Juvenile production was almost entirely the result of adult escapement and showed no indication of habitat limitations during Treatment 2.

## 8 Recommendations

### 8.1 Adult Salmon escapement

1. With the planned end of Chum and Pink outmigration monitoring during the spring, adult salmon surveys can be limited to the November to January period when Coho are spawning. While spawner estimates for Chinook, Chum and Pink have value for other fisheries management objectives, they provide little use on their own for assessing the study objectives of COQMON-7.

### 8.2 Adult Steelhead escapement

2. The primary value of Steelhead escapement monitoring is for assessing effects on egg-tofall fry survival, which remains uncertain. However, if the fall standing stock sampling ends, Steelhead escapement has little value for CMSMON-7 study objectives.

### 8.3 Juvenile salmonid standing stock

3. As much as possible, continue sampling at least 24 sites to maintain adequate precision. The primary value of late summer standing stock estimates are to be able to estimate Coho and Steelhead survival over short time intervals (eg. egg-to-fall fry, fall fry-tosmolt). The value of the estimates diminishes if the commensurate estimates are no longer obtained.

### 8.4 Smolt and fry outmigration

4. Continue to maximize the number of Coho and Steelhead recaptures at RST2 by maintaining high capture efficiency at RST2 and smolt marking at all RSTs (2-4). The length of the trapping period and the trap configurations and locations for Coho and Steelhead were adequate to include the vast majority of the smolt and fry outmigrations in recent years. A similar approach should be applied for future years. Consider removing the RST3 trap. It has had insufficient captures to generate reliable estimates.

## 10 Appendices

### 10.1 Appendices for Chapter 2

Appendix 2.1 Partial surveys, observer efficiency, and survey life
Frequent high flow events and associated high turbidity during the fall and winter spawning period contribute substantially to the uncertainty of salmon escapement estimates in the Coquitlam River (Decker et al. 2008). During 2002-2019 it was common for surveys to be postponed for as long as three weeks, or for some portions of the study area to be excluded from a survey, due to poor water visibility. In some cases, this resulted in poorly defined run timing curves for one or more species. The COQMON-07 Terms of Reference and previous analyses of spawner survey data for Coquitlam River (Macnair 2003, 2004, 2005, and 2006) do not explicitly consider negative bias in escapement estimates caused by partial surveys. In computing escapement estimates presented in this report, we corrected for negative bias arising from partial surveys by deterministically 'infilling' (i.e., approximating) counts for missed index or non-index sites prior to running the escapement model. Uncertainty from this process was not incorporated into abundance estimates. We used year-specific ratios of spawner counts in missed sites to spawner counts for the entire study area to infill missing counts for specific sites during specific surveys. First, for each year, we computed the ratio of spawners counted in each index site (and for the nonindex sites as a whole) to the total spawner count for all complete surveys. These values were then averaged across complete surveys to obtain an average ratio for each site for each year. These ratios were then used to infill missing counts for each site. For example, if, for Coho salmon, the average ratio of counts at the non-index sites to counts for the entire study area in 2009 was 0.15 , and the non-index sites were not surveyed on December 13, the total count for the study area for the December 13 survey would be expanded such that:

$$
\begin{equation*}
\text { Expanded total count }=(\text { total count } \text { sites A-E }) /(1-0.15) \tag{2.1}
\end{equation*}
$$

Information about observer efficiency and survey life is essential for the accurate estimation of salmon escapement (Irvine et al. 1992; Korman et al. 2002). During 2006-2016, we conducted 22 mark-recapture experiments to obtain estimates of observer efficiency and survey life for the four salmon species in the Coquitlam River (Table 2.2; Appendix 2.2). Note that no additional markrecapture experiments were conducted in 2016 due to the frequency of high-water events. Markrecapture experiments did not occur for Coho and Chinook until 2010 because these species are less abundant in the Coquitlam River, and it was decided at the beginning of the mark-recapture program that resources were insufficient to provide for the amount of fieldwork that would be required to capture and tag sufficient numbers of these fish. Due to the greater need for Chum and Pink escapement estimates for addressing the management question, we have discontinued the mark-recapture program for Chinook and Coho, instead shifting these resources to Chum and Pink. We attempted to minimize the length of time from when a fish arrived in the study area to when it was tagged (i.e., minimize negative bias in estimated survey life) by tagging fish near the downstream boundary of the study area, under the assumption that these would be predominately new arrivals. We also concentrated on fish holding in pools rather than those actively spawning, and avoided tagging fish exhibiting the physical characteristics of advanced sexual maturation.
10. Figures, Tables and Appendices

However, in some cases it was necessary to capture and tag salmon at locations further upstream in order to deploy an adequate number of tags and this could negatively bias survey life estimates (see Section 2.2.2.2). Beach seining was used as the primary method of capturing fish, but monofilament tangle nets were sometimes used as well when turbidity was very low. Standard Petersen disc tags were used to tag fish, with different colours used to distinguish temporal mark groups.

To provide estimates of observer efficiency (i.e., proportion of marked fish seen during a survey); we attempted to conduct a complete survey of the study area within two days of a tagging event so that the number of tags lost to mortality and emigration would be minimized. To estimate survey life, for each tagging group, we attempted to complete as many additional surveys as possible, given the constraints of river conditions and work schedules. Ideally, surveys would be repeated every 3-4 days following a tagging event, but this was not always possible. Perrin and Irvine (1990) describe several methods for estimating survey life from tagging data, two of which are applicable to this study. Both methods underestimate survey life when tagged fish are present in the study area for any length of time prior to tagging. With the first method, numbers of tagged fish from an individual tagging event that are observed on subsequent surveys are plotted against time to produce a tag depletion curve, and survey life is estimated as the area-under-the-tagdepletion curve divided by the total number of tags applied. In the second method, individually numbered tags are recovered from carcasses, and survey life is computed as the average number of days between fish tagging and carcass recovery. We estimated survey life using the area-under-the-tag-depletion curve. Fish tagging efforts during 2006-2008 suggested that the second method was not feasible in the Coquitlam River because once they die, tagged fish are quickly flushed out of the study area, and only a negligible number of tagged carcasses are recovered (a carcass fence would likely be necessary to apply this method).

In addition to causing missed surveys, variable flows and turbidity in the Coquitlam River during the salmon spawning period likely resulted in substantial variability in observer efficiency between surveys within a year, and in some cases, between years as well (see Section 2.2.2). Substantial variation in water visibility (and hence observer efficiency) among index sites during individual surveys was also common. This source of error is important because variation in observer efficiency among years that is unaccounted for will bias comparisons of adult abundance and egg-to-smolt survival among years and therefore, between flow treatments. To address this, during 2002-2018, the survey crew developed a relative index of survey conditions by subjectively 'guesstimating' observer efficiency ( $0 \%-100 \%$ ) for each index site during all surveys. It is not feasible to estimate observer efficiency using mark-recapture during each survey. Instead, the guesstimate is used to estimate observer efficiency for a survey based on the predictive relationship between surveyor guesstimates and mark-recapture derived estimates of observer efficiency (see Section 2.1.3.2).

Beginning in 2007, the survey crew also began collecting quantitative water visibility data. To index water visibility for each survey, a 1.5 m wading staff that was clearly marked at 5 cm intervals, was placed in the water column, and the depth at which the tip of the staff was no longer visible was recorded. Measurements were taken at permanently marked locations in each index site. However, based on mark-recapture experiments completed to date, estimates of water
visibility have proven to be a less useful predictor of variation in observer efficiency compared to surveyor guesstimates (Decker et al. 2012).

Appendix 2.2 Escapement model structure and parameter estimation
The escapement model consists of two main elements: i) a simple process model predicts the number of fish present on each day of the run and the departure schedule based on the total escapement and parametric relationships simulating arrival timing and survey life, and ii) an observation model simulates the number of fish counted on each survey based on the predicted numbers present and detection probabilities.

## Process model

To estimate total escapement from repeat count data, the proportion of the total run present on each survey day must be determined. This can be calculated by estimating run timing parameters that describe the cumulative proportion that has arrived and departed for each model day, which forms the process model. In the description that follows, note that lower case Arabic letters denote either model array indices (subscripts) or data. Upper case Arabic letters denote state variables (variables predicted by the model), and Greek letters denote variables that are estimated (parameters).

The proportion of the total escapement entering the survey area on day ' t ' $\left(P A_{\mathrm{t}}\right)$ of the run is predicted by a beta distribution, where $\alpha$ and $\beta$ are parameters of the beta distribution and $p_{t}$ represents the proportional day of the run. The total number of model days for Chum, Pink, Coho, and Chinook were 119 (September 3-December 30), 82 (September 1-November 21), 130 (September 20-January 27), and 99 (September 3-December 10), respectively.

$$
\begin{equation*}
P A_{t}=p_{t}^{\alpha-1}\left(1-p_{t}\right)^{\beta-1} \tag{2.2}
\end{equation*}
$$

The beta distribution is reparametrized so that $\beta$ is calculated based on estimates of the day when the peak arrival rate occurs ( $\mu$ ) and the variance (standard deviation) in the proportion of the run arriving over time ( $\sigma$ ), using the transformations:

$$
\begin{align*}
& \alpha=\mu^{*} \frac{1}{\sigma^{2}} \\
& \beta=(1-\mu)^{*} \frac{1}{\sigma^{2}} \tag{2.3}
\end{align*}
$$

For Pacific salmon, survey life, which is the number of days a fish spends in the survey area, is normally longer for fish that arrive earlier in the spawning period (Perrin and Irvine 1990; Su et al.
2001). Survey life was modeled such that it varied with the day of entry into the spawning area using a decaying exponential relationship,

$$
\begin{equation*}
S L_{t}=\lambda_{c} e^{-\lambda_{s} t} \tag{2.4}
\end{equation*}
$$

where, $S L_{t}$ is the survey life for a fish entering on day $t, \lambda_{c}$ is the maximum survey life, and $\lambda_{s}$ is the slope of the relationship. The day that a fish arriving on day $t$ has exceeded its survey life is simply $D_{t}=t+S L_{t}$, and the proportion of the run that has departed on day $t$ is,

$$
\begin{equation*}
P D_{t}=\sum_{t} P A_{t} \mid t=D_{t} \tag{2.5}
\end{equation*}
$$

The total number of fish present in the survey area on each day $\left(N_{t}\right)$ is the product of the total escapement $(E)$ and the proportion present on any survey day, estimated as the difference between the cumulative arrivals and departures on that day.

$$
\begin{equation*}
N_{t}=E\left[\int_{1}^{t} P A-\int_{1}^{t} P D\right] \tag{2.6}
\end{equation*}
$$

## Observation model

Escapement $(E)$ and arrival timing parameters $(\mu, \sigma)$, and those defining the observation process are jointly estimated by assuming that the count data arise from an over-dispersed Poisson distribution which accounts for the extra variation associated with the non-random distribution of fish on any survey (i.e., clumping),

$$
\begin{equation*}
n_{t} \sim \operatorname{Poisson}\left(N_{t} \theta_{t} e^{\varepsilon_{t}}\right) \tag{2.7}
\end{equation*}
$$

where, $n_{t}$ is the total number of fish counted on day $t, \theta_{t}$ is an estimate of the survey-specific detection probability, and $\varepsilon_{t}$ is a survey-specific deviate used to model over-dispersion in the data (McCarthy 2007; Royle and Dorazio 2008). $\varepsilon_{t}$ is drawn from a normal distribution with a mean of 0 and a precision $\tau .0$ (i.e., $\varepsilon_{t} \sim \operatorname{dnorm}(0, \tau .0)$, where $\left.\sigma .0=\tau .0^{-0.5}\right)$. The term " $\sim$ " denotes that the value to the left of the term is a random variable sampled from the probability distribution defined on the right. This equation is often referred to as the likelihood component of the model because it describes the likelihood of the data, given the parameter values. Note that $n_{t}$ will be greater than the total fish counted across sites surveyed on day $t$ if the entire survey area was not surveyed. In this case, an adjustment is required to account for areas that were not surveyed (see data description above).

Survey-specific detection probability is predicted based on the relationship between detection probability and estimated detection probability developed from mark-recapture data,

$$
\begin{equation*}
\gamma_{i}=\frac{e^{\beta_{0}+\beta_{1}{ }^{*} v_{i}}}{1+e^{\beta_{0}+\beta_{1}{ }^{*} v_{i}}} \tag{2.8}
\end{equation*}
$$

where $\gamma_{i}$ is the predicted detection probability for mark-recapture experiment $i$, and $\beta_{0}$ and $\beta_{1}$ are the constant and slope of a linear relationship predicting $\gamma_{i}$ as a function of the estimated detection probability from visual methods for that experiment $\left(v_{i}\right)$, respectively. We assume that the number of marks detected on these experiments is a binomially-distributed random variable,

$$
\begin{equation*}
r_{i} \sim d b i n\left(\gamma_{i}, m_{i}\right) \tag{2.9}
\end{equation*}
$$

where $r_{i}$ and $m_{i}$ are the number of marks detected and the total marks released for each experiment. Given estimates of $\beta_{0}$ and $\beta_{1}$, it is then possible to predict survey-specific detection probabilities $\left(\theta_{\mathrm{t}}\right)$ from equation 2.8 given a visual estimate of detection probability on each survey $\left(v_{t}\right)$.

The escapement model is implemented in a Bayesian framework and therefore requires that prior probability distributions are specified for all estimated parameters. We used uninformative priors in all cases,

$$
\begin{align*}
& E \sim \operatorname{dnorm}(2000,1.0 \mathrm{E}-6) \mathrm{I}(0,)  \tag{2.10}\\
& \mu \sim \operatorname{dunif}(0,1) \\
& \sigma \sim \operatorname{dunif}(0,10) \\
& \tau . \mathrm{o} \sim \operatorname{dgamma}(5,5) \\
& \beta_{0} \sim \operatorname{dnorm}(0,1.0 \mathrm{E}-6) \\
& \beta_{1} \sim \operatorname{dnorm}(0,1.0 \mathrm{E}-6)
\end{align*}
$$

where dnorm, dunif, and dgamma refer to normal, uniform, and gamma distributions respectively. The first and second terms in dnorm represent the mean and precision, respectively. The $\mathrm{I}(0$,$) term associated with the prior for escapement indicates that the normal distribution is$ truncated at 0 as negative escapement values are not possible. The first and second values for the uniform distributions represent the minimum and maximum values, respectively. The first and second values in the gamma distribution represent the shape and scale parameters, respectively. Values of 5 were used in each case so that model fit, as assessed by Bayesian p-values (see below), was adequate.

## Parameter Estimation and assessing model fit

Posterior probability distributions of model parameters were estimated using a Monte Carlo Markov Chain (MCMC) algorithm as implemented in WinBUGS (Spiegelhalter et al. 1999). We called WinBUGS from the R2WinBUGS (Sturtz et al. 2005) library from R (R Development Core Team 2009). We used the mean of the posterior to represent the expected value for the parameter, and the ratio of the standard deviation of the posterior to the mean as a measure of relative parameter uncertainty. The $95 \%$ credible intervals were determined from the lower 2.5 and upper 97.5 percentiles of the posterior distribution. Posterior distributions were based on a total of 2,000 MCMC samples. These samples were obtained by drawing every $2^{\text {nd }}$ sample from a total of 5,000
simulations after excluding the first 1,000 samples to remove the effects of initial values. This strategy was sufficient to achieve convergence in all cases. Model convergence was evaluated by visually inspecting the MCMC chains for evidence of non-stationarity and poor mixing.

We used posterior predicted $p$-values, often called Bayesian $p$-values, to statistically evaluate the fit of the models (Gelman et al. 2004). The concept behind this statistic is that data simulated from the model will resemble the real data if and only if the model fits the data well (Brooks et al. 2000; Gelman et al. 2004). Bayesian p-values are similar to the statistic generated from classical goodness-of-fit tests, but are based on multiple measures of discrepancy determined from the posterior distribution of predictions, rather than the single best-fit prediction determined by maximum likelihood estimation in the latter case. Bayesian $p$-values are computed by replicating a data set based on the model predictions for each MCMC trial. Measures of discrepancy between the replicated data and model predictions (D`), and observed data and model predictions (D), are then compared. The fraction of MCMC trials were \(\mathrm{D}^{`}>\mathrm{D}\) is the Bayesian $p$-value. Low $p$-values indicate the model under-fits the data, that is, there is too much scatter around the curve describing the number of fish observed over the run, either because the run-timing model is not flexible enough (under-parameterized) and/or does not explain enough of the variability in the data given the assumed error model. High $p$-values indicate that the model over-fits the data, that is, the model explains more variation than expected, either because the run-timing model is too flexible or because the assumed error structure is too complex. Bayesian p-values of approximately 0.5 indicate an ideal fit. We used the Freeman-Tukey statistic as the measure of discrepancy as recommended by Brooks et al. (2000) for the analysis of mark-recapture models. This measure assigns less weight to outcomes with small expected counts (similar to Pearson's $\chi^{2}$ ), and provides more robust assessments of model fit when outcomes are close to zero as is sometimes the case with count data.

Appendix 2.3 The number of hatchery Chinook smolts released in the Coquitlam River 2004-2018 (Scott Ducharme, DFO).

| Release year | Number |
| :---: | :---: |
| 2004 | 38,000 |

Appendix 2.9 An example of diagnostic graphs used to evaluate model fit to the observed data (Coho 2008). Top-left graph shows fit of predicted run timing curve (line) to unadjusted counts of spawners over time. Top-right shows relationship of predicted to observed counts with $95 \%$ credible intervals for predicted counts. Lower-left graph shows variation in predicted observer efficiency across surveys. Lower-right graph shows the regression relationship between surveyor guesstimates of observer efficiency (horizontal axis) and mark-recapture derived estimates of observer efficiency (vertical axis), with $95 \%$ credible intervals shown for the estimated regression slope.

### 10.2 Appendices for Chapter 3

Appendix 3.1 Discharge ( $\mathrm{m}^{3} / \mathrm{s}$ ) in Coquitlam River at Port Coquitlam during Steelhead spawning period in 2005 2020 (Water Survey of Canada station 08MH002).

10. Figures, Tables and Appendices

## 131

Appendix 3.2 Survey dates with raw counts of Steelhead redds, estimated new redds, and live adult counts for all surveys during 2005-2021. Estimated new redds includes the sum of the raw count and the estimated number of redds that were constructed and then obscured by substrate movement prior to a scheduled survey, based on a redd survey life model.

| Year | Survey date | Days since previous survey | Raw count of new redds | Estimated \# new redds | \# Live adults observed |

### 10.3 Appendices for Chapter 4

Appendix 4.1 Methods for night snorkeling
Snorkeling sites were chosen using a simple (non-stratified) systematic sampling design (SSS). Sampling was not stratified by reach or habitat type due to the limited number of sites sampled. During 2007-2013, the 10 sites originally selected in 2006 were re-sampled, and an additional two sites were added in Reach 4 to maintain a uniform sampling interval of $\sim 0.85 \mathrm{~km}$ (Figure 4.1). The additional 12 sites added in 2014 (for a total of 24 sites) were distributed equidistance between the existing sites. Initial site selection was accomplished using a hand-held GPS unit to determine the straight-line distance from Patricia Footbridge to Coquitlam Dam, and dividing this distance by the total number of sites to obtain a uniform sampling interval. Each site was 25 m in length and spanned the entire stream channel. If the stream was split into two or more wetted channels at the selected site location, the entire wetted width of all channels was surveyed as part of the 25 m site to ensure that the site accurately represented available habitat for a particular channel cross-section. Snorkeling surveys were scheduled for early September when precipitation is normally low and target discharge from Coquitlam Dam was $0.8 \mathrm{~m}^{3} / \mathrm{s}$ under Treatment 1 (2006-2008) and $2.2 \mathrm{~m}^{3} / \mathrm{s}$ under Treatment 2 (2009-2020). Snorkeling counts were performed once at each site by a two-person crew. Counts were performed a four-hour period beginning 0.5 hours after dusk because numerous studies have shown that daytime concealment behaviour is common in juvenile salmonids (e.g., Bradford and Higgins 2000 and references therein). To illuminate the sampling sites at night, snorkelers used handheld dive lights that cast diffuse rather than direct beams to minimize the disturbance to fish. Snorkelers surveyed the stream's entire wetted width, with each snorkeler entering the site at its downstream end and systematically sweeping in an upstream direction the area between his bank and the agreed upon mid-point of the site. Regular communication between snorkelers was essential to avoid duplicating counts, particularly in the instances where fish were present in mid-channel areas.

To address the potential concern that age-0+ salmonids, which occupy shallow, nearshore habitats, would be difficult to survey effectively by snorkeling (Griffith 1981; Campbell and Neuner 1985; Hillman et al. 1992), snorkelers delineated areas that were too shallow to view from an underwater position. Following the completion of an underwater search of the remainder of the site, conducted a separate visual survey of these areas on foot with masks removed. During the 2006 pilot study it was evident that small fish along the stream margin remained relatively stationary at night and could be identified to species and size class, and if necessary, could be captured with a small net to confirm observations. At sites where these shallow areas were not well delineated from the rest of the site, and the risk of double counting fish was apparent, the two snorkelers worked parallel to one another, with one person searching shallow near-shore areas, and the other searching adjacent offshore areas. Each person communicated movements of detected fish to the other. This procedure was then repeated for the other half of the site. Other studies have shown that streamside visual counts can be excellent predictors of juvenile salmonid abundance when calibrated using more accurate methods (Bozek and Rahel 1991; Decker and Hagen 2009). Snorkelers identified to species and visually estimated the fork lengths of all fish observed and recorded their observations in waterproof notebooks. To aid in the estimation of fish

## 10. Figures, Tables and Appendices

lengths, snorkelers drew ruled scales on the cover of their notebooks. Snorkelers were typically able to hold the notebooks within 30 cm of a fish to measure its length without disturbing it. Although there was no attempt to assess the accuracy of fish length estimates made by snorkelers, in two similar studies (Korman et al. 2011; Decker and Hagen 2009) in which some of the same snorkelers from this study participated, it was found that snorkelers could estimate juvenile fish lengths relatively precisely with little negative or positive bias ( $\mathrm{R}^{2}$ values for regressions of estimated versus measured fork length ranged from 0.94 to 0.97 ).

Appendix 4.2 Mark-recapture experiments to estimate snorkeling detection probability
To derive population estimates from snorkeling counts, an estimate of snorkeling detection probability (proportion of total fish at a site that snorkelers detect) is also required. The juvenile standing stock study design calls for 2-4 mark-recapture experiments to be completed during each year until enough data are obtained to provide a reliable model of detection probability. We conducted a total of 23 mark-recapture experiments during 2007-2013 towards this end. By distributing the mark-recapture experiments over several years and equally among the 12 annual sampling sites, bias resulting from differences in detection probability among years or habitat types was minimized. Now with well-defined detection probability information for Coho, age-0 fry and age-1 Steelhead parr, further mark-recapture experiments were suspended in 2014. Further mark-recapture experiments would not increase the precision of the standing stock estimates as much as doubling the number of index sites would, by possibly shifting effort from mark-recapture to index sampling. This prevents further refinements to the age-2 Steelhead parr detection probability estimate but this age-class has minimal use for estimating survival or other productivity metrics because a portion of this year-class undergoes smolting prior to fall surveys.

To estimate detection probability discretely for each target species/age-class at a sampling site, one night prior to conducting the normal snorkeling survey, a single snorkeler captured and marked fish throughout the site using one or two large aquarium nets affixed to handles of $\sim 80$ cm in length. The snorkeler searched for and captured fish throughout the site with the goal of marking 10-20 individuals for Coho fry, and for each length class of Steelhead (see below). Minimizing disturbance to marked and unmarked fish was a primary goal of the marking methodology. Captured fish were handed to a second crewmember on shore, who immediately measured the fish (fork length to nearest 5 mm ), marked it, and returned it to its original location after the snorkeler had moved on. Anticipating that detection probability would differ for smaller and larger juvenile Steelhead over the size range occurring in the Coquitlam River (Hagen et al. 2011; Korman et al. 2011), we used colour-coded tags to obtain five discrete mark groups for Steelhead ( $40-50 \mathrm{~mm}, 50-69 \mathrm{~mm}, 70-99 \mathrm{~mm}, 100-140 \mathrm{~mm}$, and $>140 \mathrm{~mm}$ ). The smaller two length classes represent age- $0+$ fry, while the larger three represent age- $1+$ and $2+$ parr. Marking consisted of inserting a custom-made tag into the fish's back at the insertion of the dorsal fin. Tags consisted of size 16-20 barbed fish hooks (size 16 for fish > 140 mm fork length, size 18 for fish $70-140 \mathrm{~mm}$, and size 20 for fish < 70 mm ), with a length of coloured plastic chenille ( $8-15 \mathrm{~mm}$ depending on fish size) attached at the hook eye with heat shrink tubing (Hagen et al. 2011). Tags were sized so that snorkelers could readily detect a mark on a fish, without the mark increasing the likelihood of the fish being seen relative to an unmarked one. Captured fish were not anaesthetized because of the uncertainty associated with behavioural effects from the anaesthetic. During the re-sighting event snorkelers recorded marked and unmarked fish separately.

Snorkeling detection probability was estimated for individual sites, species and length classes by dividing the number of marked fish seen by the number marked (R/M). This type of mark-recapture study assumes a closed population, whereas our sites were not enclosed with nets. However, over sufficiently short time periods, if study animals restrict their movements to

## 10. Figures, Tables and Appendices

a defined area, physically open sites can be treated as closed without introducing significant bias (Pollock 1982; Bohlin et al. 1989; Mitro and Zale 2002). We chose to conduct the underwater surveys 24 hours after marking because we considered this to be the shortest time period that would still allow fish to recover from marking and complete a diurnal cycle of movement and redistribution within the site, but would minimize movement from the site. We investigated the assumption of site closure by surveying an additional distance of approximately half the site length adjoining both the upstream and downstream site boundaries, so that the total distance surveyed for marks was approximately two times the length of the original site where fish were marked. Marked fish that had moved beyond the original site boundaries were recorded separately. The number of marked fish that emigrated from the original site was estimated as the number of marks observed in the adjoining sections divided by R/M.

Appendix 4.3 Estimation of fish standing stocks and mean densities
There are predominately three age-classes of juvenile Steelhead (age- $0+$, $1+$ and $2+$ ) in the Coquitlam River during late summer; older fish are relatively uncommon and likely to be resident rainbow trout. We computed separate population statistics for each of the three ageclasses, and also pooled age- $1+$ and age- $2+$ Steelhead data to compute aggregate population statistics for Steelhead parr. Steelhead ages were estimated based on an analysis of length frequency histograms generated from both the electrofishing and snorkeling data, as well as from length-age data derived from Steelhead smolts from the Coquitlam River (see Section 5.2.2). A small proportion of juvenile Coho salmon spend two winters in the Coquitlam River prior to migrating seaward, but we did not stratify our standing stock estimates for Coho by age.

To estimate juvenile standing stocks for the entire study area, and to quantify uncertainty in these estimates, we relied on a modified version of an HBM originally developed by Korman et al. (2010) to estimate juvenile Steelhead abundance in the Cheakamus River. Their model is in turn a derivation of a model originally proposed by Wyatt (2002, 2003). The sampling (night snorkeling) and calibration methods (mark-recapture) employed in the Korman et al. (2010) study were similar to those used in this study. The hierarchical structure of the HBM approach is well suited to two-stage sampling designs where it is necessary to combine error sources arising at different levels or hierarchies of the sampling design (Wyatt 2002).

The mark-recapture experiments indicated that the snorkeling detection probability for Steelhead was size-dependant (see Sections 4.1.4 and 4.2.1.1). In order to account for this, the HBM incorporates stratification by generating independent standing stock estimates for six Steelhead age-class/size-class strata ( $0+<50 \mathrm{~mm} ; 0+50-70 \mathrm{~mm} ; 1+70-99 \mathrm{~mm} ; 1+100-149 ; 2+$ $100-149 \mathrm{~mm}$; and $2+>149 \mathrm{~mm}$ ). To generate a standing stock estimate for a particular Steelhead age-class, the HBM sums estimates across the appropriate size-class strata.

Descriptions of all parameters, variables, constants, subscripts and equations used in the HBM are provided in Appendices 4.1 and 4.2. For the observation (detection) component of the HBM, the number of marked fish observed at snorkeling mark-recapture site $i$ during the recapture event was assumed to be binomially distributed and to depend on the detection probability and number of marks released during the initial marking event (Appendix 4.2, Equation 4.1). The between-site variation in detection probability at mark-recapture sites was assumed to follow a beta hyper-distribution (Equation 4.2). The number of fish observed at index site $j$ (regular sampling site as opposed to a mark-recapture site) was assumed to be binomially distributed and to depend on abundance at the site and a randomly selected detection probability taken from the hyper-distribution of detection probabilities (Equations 4.3 and 4.4). The process component of the HBM assumes that variation in juvenile abundance across sample sites follows a Poisson/log-normal mixture. That is, abundance within a site is Poissondistributed with a mean equal to the product of fish density and length of stream that was sampled (Equation 4.5), and the log of fish density across index sites is normally distributed (Equation 4.6).

## 10. Figures, Tables and Appendices

The total standing stock for the study area (Equation 4.9) was computed as the sum of the standing stock estimates from the 12 sampled index sites (Equation 4.7) and the standing stock estimate for the unsampled stream length within the stratum (Equation 4.8). The latter value was computed as the product of the back-transformed mean density from the lognormal density hyper distribution $\left(\mu_{\lambda}\right)$ with lognormal bias correction $\left(0.5 \tau_{\lambda}\right)$, and the length of the unsampled portion of the stratum.

Posterior distributions of parameters and standing stock estimates from the HBM were estimated using WinBUGS (Spiegelhalter et al. 1999) called from the R2WinBUGS library (Sturtz et al. 2005) from the " $R$ " statistical package (R Development Core Team 2009). Uninformative prior distributions for hyper-parameters were used if possible for size-specific strata. As well, an uninformative uniform distribution, and an uninformative half-Cauchy distribution were used as priors for the mean and standard deviation of the hyper-distribution for age-, and size-specific detection probability, respectively (Appendix 4.2, Equations 10 and 11, respectively). An uninformative normal prior was used for the mean of the hyper-distribution for $\log$ fish density, and an uninformative half-Cauchy distribution was used as a prior for the standard deviation of log fish density (Equation 4.12). The half-Cauchy prior, also referred to as a 'folded $t$ distribution', is useful in cases where it is difficult to estimate the variance of hyperdistributions in hierarchical Bayesian models due to limited information in the data (Gelman 2006).

In a few cases, estimates of the variance in the hyper-distributions of detection probability or $\log$ fish density were unstable based on these uninformative priors. This occurred because there were either too few fish of a specific size class marked during the mark-recapture experiments to reliably estimate the standard deviation in detection probability ( $\tau_{\theta, g}$, Equation 4.11), or the number of fish of a specific size class present in the index sites was too low and variable to reliably estimate the standard deviation in fish density among the index sites ( $\tau_{\lambda}$, Equation 4.13).

In these cases, which are described in Appendix 4.3, rather than estimate $\tau_{\theta, g}$ and $\tau_{\lambda}$, we used fixed values that were equal to the estimated parameter values for an adjacent size class. The means of the hyper-distributions ( $\mu_{\theta, g}$ and $\mu_{\lambda, s}$; Equations 4.10 and 4.11) were still estimated separately for each fish size class.

Posterior distributions were estimated by taking every second sample from a total of 10,000 simulations after excluding the first 1000 'burn in' samples. This sample size and sampling strategy was sufficient to achieve adequate model convergence in all cases. Model parameters were estimated in two stages. In the first stage, the posterior distributions of site-specific detection probabilities and hyper-parameters were estimated (Equations 4.1 and 4.2). In the second stage, posterior distributions for the parameters in the population model were estimated. The $\theta_{\mathrm{j}, \mathrm{g}}$ values required for the population model were simulated from beta hyper-distributions whose parameters were determined from the median values of the posterior distributions estimated in the first stage. This two-phased estimation approach reflects our two-stage sampling design, and ensures that the hyper-distribution for detection probability is not influenced by data from the regular snorkeling index sites. Ideally, we could have sampled from
the full range of detection probability hyper-distributions of detection probability in the second estimation phase. This latter approach, which integrates over the full uncertainty in detection probability hyper-parameters, increases computational time by two to three orders of magnitude. During the initial model development of a similar HBM for the Cheakamus River, Korman et al. (2010) compared uncertainty in juvenile Steelhead standing stock estimates based on the median versus fully integrated two-phased estimation approaches and found the increase in uncertainty under the latter approach was relatively modest (a few \%). Based on their results, we adopted the more computationally efficient median approach. Korman et al. (2010) also used computer simulations to evaluate the extent of bias in standing stock estimates and hyper-parameters generated from the Cheakamus River HBM and found that bias to be negligible in all cases.

To describe the precision of the standing stock estimates in this report, we have used percent relative error, which we computed as the average half credible interval (upper $95 \%$ credible limit minus the lower credible limit divided by two and then divided by the mean and expressed as a percentage Krebs 1999). It is important to note that standing stock estimates and confidence intervals reported here will differ in future years' reports if estimates of size-specific snorkeling detection probability are further refined by additional mark-recapture experiments, or in the case where site-specific habitat or environmental variables (e.g., temperature, mean depth, etc.) are incorporated into the observation component of the HBM models, if they are found to be significant predictors of snorkeling detection probability.

Fish/km was calculated by dividing the standing stock estimate by the total length of the Coquitlam River ( 10.3 km ). Fish $/ 100 \mathrm{~m}^{2}$ was calculated as the average density of the sampling sites. This is because the total area of the studied zone of the Coquitlam River is not assessed each year.

Appendix 4.4 Definition of variables of the hierarchical Bayesian model used to estimate juvenile Coho and Steelhead abundance in the Coquitlam River system. Index sites refer to the 12 sites in the Coquitlam River where fish abundance is sampled each year by night snorkeling. Fish size strata (subscript g) apply only to Steelhead (see Section 4.1.5).

| Variable | Description |
| :--- | :--- |
|  |  |
|  |  |
| Data |  |
| $\mathrm{r}_{\mathrm{i}, \mathrm{g}}$ | Marks detected at snorkeling mark-recapture site i , fish size strata g |
| $\mathrm{m}_{\mathrm{i}, \mathrm{g}}$ | Marks released at mark-recapture site i, strata g |
| $\mathrm{c}_{\mathrm{j}, \mathrm{g}}$ | Fish detected at index site j for strata g |
| $\mathrm{l}_{\mathrm{j}}$ | Stream length for index site j |
| Site-Specific Parameters |  |
| $\theta_{\mathrm{i}, \mathrm{g}}$ | Estimated detection probability at mark-recapture site i for fish size strata g |
| $\theta_{\mathrm{j}, \mathrm{g}}$ | Simulated detection probability for index site j for strata g |
| $\lambda_{\mathrm{j}}$ | Estimated density $($ fish $/ \mathrm{m})$ at index site j |

Hyper-Parameters

| $\mu_{\theta, \mathrm{g}}$ | Mean of beta hyper-distribution for detection probability for strata g |
| :--- | :--- |
| $\tau_{\theta, \mathrm{g}}$ | Precision of beta hyper-distribution for detection probability for strata g |
| $\mu_{\lambda}$ | Mean of normal hyper-distribution for log fish density |
| $\tau_{\lambda}$ | Precision of normal hyper-distribution for log fish density |

## Derived Variables

| $\alpha_{i, g}$ | Parameter for beta hyper distribution of detection probability for strata g |
| :---: | :---: |
| $\beta_{\mathrm{i}, \mathrm{g}}$ | Parameter for beta hyper distribution of detection probability for strata g |
| $\mathrm{N}_{\mathrm{j}, \mathrm{g}}$ | Abundance at index site j for strata g |
| Ns | Total abundance across all index sites |
| Nus | Total abundance in unsampled stream length |
| Nt | Total abundance in the Coquitlam River study area |
| Indices and Constants |  |
| i | Index for snorkeling mark-recapture site |
| j | Index for snorkeling index site |
| g | Index for fish size strata |
| $\mathrm{l}_{\mathrm{j}}$ | Shoreline length for index site j |
| L | Total shoreline length for the Coquitlam River study area |

Appendix 4.5 Equations of the hierarchical Bayesian model used to estimate juvenile Steelhead abundance in the Coquitlam River. See Appendix 4.1 for definitions of model parameters, constants, and subscripts. Lower case Arabic letters denote data or indices (if subscripts). Capital Arabic letters denoted derived variables, which are computed as a function of estimated parameters. Greek letters denote estimated parameters. Parameters with Greek letter subscripts are hyper-parameters.

& \sigma_{\lambda} \sim \operatorname{dhcauchy}(0,0.5) \tag{4.12}
\end{align*}
$$

(4.13) $\quad \tau_{\lambda}=\sigma_{\lambda}^{-2}$

Appendix 4.6 Summary of data deficiencies and alternate approaches taken with respect to estimation of parameters and hyper-distributions in the Hierarchical Bayesian Model (HBM) used to estimate juvenile Steelhead and Coho standing stocks in the Coquitlam River during 2006-2019.

1. Large-sized Steelhead parr ( $>140 \mathrm{~mm}$ ) and small-sized Steelhead fry ( $<50 \mathrm{~mm}$ ). For these size categories of Steelhead, there were relatively few fish marked and resighted at the markrecapture sites, and numbers observed by snorkelers in the index sites were low and quite variable. This led to an insufficient amount of data for the HBM to reliably estimate standard deviation in snorkeling detection probability and fish density among index sites. These deficiencies were addressed by substituting parameter estimates for medium-sized Steelhead parr ( $100-140 \mathrm{~mm}$ ) in the case of large-sized Steelhead, and parameter estimates for large-sized Steelhead fry ( $50-69 \mathrm{~mm}$ ) in the case of small-sized Steelhead fry.
2. Coho fry in 2006 and large -sized Steelhead fry ( $50-69 \mathrm{~mm}$ ) in 2007. In these cases, numbers observed by snorkelers in the index sites were low and quite variable, leading to an insufficient amount of data for the HBM to reliably estimate standard deviation fish density among index sites. These deficiencies were addressed by substituting the mean of standard deviation estimates for other years for these species/size classes.

Appendix 4.7 Summary of habitat data for night snorkeling and day electrofishing sites in Coquitlam River in 2021.

### 10.4 Appendices for Chapter 5

Appendix 5.1

### 5.1 Methods

### 5.1.1 Coho and Steelhead smolt enumeration

Downstream migrating Coho and Steelhead smolts were captured at three locations in the Coquitlam River mainstem (RST2, RST3, RST4) using rotary screw traps (RST), and at the outlets of four constructed off-channel sites using full span weirs (Figure 5.1). Mark-recapture data collected at RSTs were used to estimate smolt numbers for three mainstem reaches and for the entire Coquitlam River upstream of Port Coquitlam (Figure 5.1).

Our approach assumes all fish passing full span weirs are captured (capture efficiency = $100 \%$ ) but that only a portion passing each RST site are caught (capture efficiency $\neq 100 \%$ ). We use variations of the Peterson two-sample mark-recapture method (Seber 1982) to estimate the proportion of fish passing each RST that are caught and not caught. This information is then used to adjust the catch from the RST site by the capture efficiency of the trap. For example, if an RST caught 50 of the 100 marked fish released upstream, the trap would have a $50 \%$ capture efficiency or that the trap captures half of the fish that pass by. And if a total of 1,000 fish were captured at that same trap, then we would estimate that another 1,000 fish passed without capture for a total estimate of 2,000 fish passing the trap. Our marking approach divides the outmigration period into a number of time periods (strata) that allows for individual estimates of capture efficiency for each stratum.

The Peterson mark-recapture method relies on several assumptions in order to produce unbiased estimates. Arnason et al.(1996) lists the three for time stratified mark-recapture as:

Closed population - There is no recruitment, emigration or mortality between sampling events.
No tag loss - Tag loss can take several forms in the context of this study. Tagging can induce mortality. Tags can be lost or go undetected. This includes that marks remain identifiable when marked fish pass the recapture site.

Equal catchability - That the probability of capturing a fish at the recapture sites is independent of whether it was marked or not.

### 5.1.1.1 Location and description of downstream traps

Ideally, RST trapping would be conducted at the downstream end of Reach 1 at Port Coquitlam (the upper limit of tidal influence), so as to estimate smolt yield for the entire study area of the Coquitlam River. However, because of problems with site security, and given the limited number of sites that possess adequate water depth and velocity, RSTs were not installed at the downstream reach boundaries (Figure 5.1). Until 2005, our lowermost trapping site (RST2) was located just downstream of the upper boundary of reach $2 \mathrm{a}, 5.1 \mathrm{~km}$ upstream of the

Reach 1 downstream boundary (Figure 5.1). The 2.6 km long section between RST2 and RST3 immediately upstream includes most of reach 2 b and the upper portion of reach 2 a , and is referred to in this report as reach 2. For 2006-2018, the RST2 site was moved 600 m downstream (a high water event infilled the former trapping site), increasing the length of the 'reach 2' section to 3.2 km . In 2018, the RST3 site was moved 300m upstream of its previous location to improve access. We refer to the 2.7 km long section between RST3 and RST4 as reach 3 (Figure 5.1), but it should be noted that this section also includes the upper 900 m portion of reach 2 b . The uppermost trap site (RST4) was installed 1.6 km below the Coquitlam Dam, trapping a section that includes all but 100 m of reach 4 (Figure 5.1) ${ }^{2}$.

In annual reports prior to 2009, smolt yield for the entire study area included the 4.5 km of reach 1 and 2 downstream of the lowest trapping site. To allow for this, we approximated smolt numbers for reach 1 and the portion of reach 2a downstream of RST2 ( 4.5 km of habitat) based on extrapolation of smolt densities in reach 2 immediately upstream of RST2 site (i.e., reach 2 b and a portion of reach 2 a ). However, this represents a potentially serious source of bias depending on the degree to which actual smolt densities in the 4.5 km section downstream of RST2 differ from those immediately upstream. For example, extrapolating relatively high Steelhead smolt density in reach 2 in $2008\left(3.1\right.$ smolts $\left./ 100 \mathrm{~m}^{2}\right)$ to the 4.5 km section downstream, resulted in an estimate of 9,245 Steelhead smolts for the Coquitlam River mainstem based on 5,480 smolts passing RST2 (see Decker et al. 2009). This suggests that the unsampled lower 4.5 km section produced $41 \%$ of mainstem Steelhead smolts, despite relatively low densities of Steelhead redds (Figure 3.2) and parr (Figure 4.3). With the exception of Chum, spawning occurs primarily upstream of RST2 for the four species included in the monitoring program (Coho: $92 \%$; Chum: $50 \%$; Pink: $74 \%$; Steelhead: $88 \%$; mean values across years). To eliminate potential bias associated with extrapolation of smolt numbers downstream of RST2, estimates of smolt yield for the Coquitlam River in all years reported here are for the 7.5 km long section upstream of RST2 only, rather than for the entire 12.0 km long study area extending from the dam to the downstream boundary of reach 1 (see Figure 5.1). With respect to stock-recruitment relationships, and egg-to-smolt survival estimates, this assumes that all juvenile recruits from spawning upstream of RST2 will remain upstream of RST2 until they emigrate as smolts. However, downstream movement of pre-smolt juveniles occurs in the spring as evidenced by significant catches of age-1 Steelhead parr at the RSTs (and likely occurs during other portions of the years as well).This results in some degree of negative bias in our estimates of egg-to-smolt survival.

There are four large constructed off-channel sites (Or Creek, Grant's Tomb, Overland Channel, and Archery Pond) located between Coquitlam Dam and RST2, totaling about 27,000 $\mathrm{m}^{2}$ of habitat (Figure 5.1). The enumeration of smolts from the off-channel sites was necessary for two reasons: 1) to distinguish between smolt production in constructed off-channel habitat that is largely unaffected by flow releases from the dam, and production in natural mainstem

[^2]
## 6. Smolt and Fry Outmigration

habitat that is directly affected by flow releases; and 2) to provide additional marked smolts to improve the precision of smolt abundance estimates for downstream mainstem reaches.

We relied on total counts at full-span downstream weirs (Conlin and Tutty 1979) to estimate smolt yield from three of the sites (Or Creek, Grant's Tomb, Overland Channel). Overland Channel consists of two ponds that are connected, with each pond also having its own outlet channel. We installed an inclusion fence at the outlet of the upper pond at the Overland Channel sites, forcing all smolts to migrate through a single weir installed in the outlet of the lower pond. Detailed descriptions of these sites and the design of the downstream weirs can be found in previous reports (e.g., Decker 1998).

A full span weir was used to enumerate smolts leaving Archery Pond. This approach was used prior to 2008 and 2014 onward. During 2009-2013, the method switched to use markrecapture by minnow trapping to estimate pre-smolt abundance. This was to shift resources to the sites that historically produced greater numbers of smolts. However, during 2013, too few Coho pre-smolts were captured in Archery Pond for population estimates ( 6 fish with 200 "Gee" brand wire mesh minnow traps baited with 2 g of preserved roe and set for 24 hours).

### 5.1.1.2 Downstream trap operation

In 2020, one 2.4 m diameter RST was operated at the reach 4 trapping site (RST4), one 1.8 m RST was operated in reach 3 (RST3) and two 1.8 m RSTs (RST2; Figure 5.1) were operated in close proximity to one another in reach 2. Using two smolt traps at the RST2 location was intended to increase the capture efficiency, which is key to produce precise mainstem population estimates. A 2.4 m diameter RST was used previously at the reach 4 site, with the exception of 2018. The decision to return to the 2.4 m RST at this site was based on the low capture efficiency in 2018. Screening used on all of these RSTs was 12 mm in diameter on rotating drum and 9 mm for retention box. An additional 1.3 m diameter RST (RST2.2) with 2.5 mm mesh size was operated at the RST2 location to capture outmigrating Chum and Pink fry.

The objective is for all off-channel weirs and the mainstem RSTs to operate continuously from early-April until mid-June, with the exception of RST2.2, used for Chum and Pink enumeration, which starts operation in early-March. Table 5.1 lists the dates traps were installed, decommissioned and the start dates of marking strata. During some years, one or more RSTs were installed as early as February to monitor for early outmigration but operation was sporadic and was not designed to produce reliable population estimates for the period prior to full operation. Thus, data from the early monitoring was not used in the outmigration estimates. All juvenile fish captured at the weirs and RSTs were identified to species, counted and measured for fork length (nearest mm). Unmarked Coho and Steelhead smolts and Steelhead parr were injected with Visual Indicator Elastomer (VIE) to apply a unique mark identifying capture period and location (see Section 5.1.1.3). Prior to 2018, only fin clips were used to mark for release period and location. To minimize behavioural effects from handling, every effort was made to reduce the stress on fish during the sampling and marking process, and, once recovered, fish were immediately released.

## 6. Smolt and Fry Outmigration

We assumed that all downstream migrating Coho larger than 60 mm fork length were smolts. Steelhead smolts in the Coquitlam River range from two to four years in age. We assumed that all Steelhead $120-230 \mathrm{~mm}$ in length were seaward migrating smolts, while fish $<120 \mathrm{~mm}$ were yearlings and smaller age-2 fish that would remain in the river for at least one more year (see section 5.3.2 for a discussion of this assumption). Frequency histograms of Steelhead fork length from previous years suggest that most two-year old Steelhead smolts are greater than 120 mm in length during the spring migration. We recorded daily catches of Steelhead parr ( $<120 \mathrm{~mm}$ ) caught at each downstream trapping site, but, because there was no way of knowing what proportion of the total parr population these downstream migrants represented, we did not attempt to estimate parr populations by mark-recapture. Conversely, it was reasonable to assume that all smolts were downstream migrants. However, trapping personnel have noted marks from previous years on captured Steelhead smolts, indicating that at least a small portion of Steelhead $>120 \mathrm{~mm}$ that are counted as smolts are actually parr that remain in the river for an additional year. This resulted in some degree of positive bias in estimates of annual smolt yield. During 2005-2020, we collected scale samples from randomly selected Steelhead captured at the RSTs in order to estimate the proportions of age-2+ and age$3+$ fish in the smolt population. This was necessary for estimating egg-to-smolt survival since the progeny from one spawning event will outmigrate after either two or three winters in freshwater.

### 5.1.1.3 Differential marking by period and initial capture location

As in previous years, we estimated smolt abundance in mainstem reaches of the Coquitlam River using a stratified mark-recapture method (Arnason et al. 1996, Schwarz et al. 2009). Significant temporal variation in capture efficiency (\% of marked smolts recovered) is common when mark-recapture methods are used to estimate the abundance of a migrating population (Seber 1982), and stratifying marking by period allows for unbiased estimates when temporal variation in capture efficiency is expected.

To provide distinct mark groups over time, all unmarked Coho and Steelhead smolts captured at the off-channel weirs and the upstream RSTs (RST3, RST4) were differentially batch-marked according to date (week) and location of initial capture (Table 5.1). In addition, unmarked Steelhead captured at RST2 were uniquely marked so that they could be released upstream ( $\approx 1 \mathrm{~km}$ ) rather than downstream in order to increase the size of the marked population available for capture at RST2. Similarly, for the uppermost RST site (RST4; Figure 5.1), marked populations of Coho and Steelhead originating from the Grant's Tomb off-channel site were augmented by marking and releasing captured mainstem smolts at a site about 1 km upstream of RST4.

Prior to 2018, the unique mark types consisted of a small clip at one of several fin locations. In 2018, VIE was introduced based on its long mark-retention, ease of distinguishing mark types and greater number of unique mark types possible than with fin clips. VIE used six colours (green, pink, orange, yellow, red and blue) injected into the caudal fin or a clear tissue deposit posterior to the eye. The duration of each marking period was set at 7 days for the 2020 season. This is a departure from years prior to 2018 in which the duration was based on achieving a minimum recapture target of 40 Coho and 10 Steelhead smolts from each mark group and

## 6. Smolt and Fry Outmigration

trapping location. There were two reasons for this change. First, we planned to use a different model to estimate time-stratified capture data that benefits from set length marking strata as well as a higher number of marking strata. Second, VIE allows for a larger number of marking strata than fin clips. To evaluate that detection rates were similar for VIE and fin clips, we compared recapture rates for each method over two weeks. To do this, half the fish at each trap received the VIE mark and the other half received a combination of caudal clips. Capture efficiency for each species, and trap were then tested whether they were significantly different.

Coho and Steelhead smolts as well as Steelhead fry were also given a unique mark based on where they were initially captured (see Appendix 5.1 and paragraph below). This mark served two purposes. First, it allowed for separate population estimates for mainstem and off-channel habitats. Since all off-channel fish were marked, all unmarked fish captured at the RSTs were assumed to be of mainstem origin and then could be used to estimate the number of mainstem fish passing each RST. The second purpose was to evaluate whether fish marked at off-channel weirs had similar capture efficiencies at each RST as mainstem fish. If they were similar, both could be used to estimate the number of unmarked smolts (mainstem origin) passing each RST. If they were different, then only mainstem marked fish would be used. This is more of an issue for Coho than Steelhead since very few Steelhead smolts originated from the off-channel sites while a large proportion of marked Coho smolts do. This is a concern for Coho because previous work in the Coquitlam River has shown significant differences in capture efficiencies for smolts originating from these two habitat types (Decker and Lewis 2000; Decker et al. 2003), suggesting that estimates based on combined marked populations could be biased. By separately analyzing marking and recovery data for these different mark groups, we were able to evaluate the capture efficiency of smolts marked as originating from mainstem versus off-channel habitat passing the same RST.

Since the precision of mark-recapture estimates generally improves with the number of smolts marked, it is advantageous to generate estimates based on combining data for different mark groups. To decide which spatial mark groups could be included in the final mark-recapture dataset for a particular RST, we used the following rationale and statistical tests:

1. We assumed that capture efficiency for unmarked smolts from the mainstem would be better approximated by observed capture efficiency for marked mainstem smolts than by observed capture efficiency for marked off-channel smolts, although we were not able to test this (see section 5.1.1.5),
2. Using Fisher's exact test, we tested whether overall capture efficiency (pooled data for temporal mark groups) differed ( $\mathrm{P}<0.05$ ) for marked smolts from the off-channel and mainstem areas. For example, capture efficiencies (CE) for off-channel and mainstem smolts at RST2 were computed as:

## 6. Smolt and Fry Outmigration

$$
\begin{equation*}
\frac{\sum_{i}^{6} R_{\text {off-channel }, i}}{\sum_{i}^{6} M_{\text {off-channel, } i}} \text { and } \frac{\sum_{i}^{6} R_{R S T 2, R S T 3, R S T 4, i}}{\sum_{i}^{6} M_{R S T 2, R S T 3, R S T 4, i}} \tag{5.1}
\end{equation*}
$$

where
Roff-channel,, $\mathrm{i}=$ number of marked off-channel smolts from marking period i that were recaptured at RST2
$\mathrm{M}_{\text {off-channel, } \mathrm{i}}=$ number of off-channel smolts marked during marking period i
$\mathrm{R}_{\text {RST1,RST2,RST3 }}=$ number of marked mainstem smolts (all mainstem trapping locations summed) from marking period ithat were recaptured at RST2
$\mathrm{M}_{\text {RST2, RST3,RST4,I }}=$ number of mainstem smolts that were marked during marking period i
3. If we failed to detect a difference in CE, all mark groups were considered in the dataset used to compute the final mark-recapture estimate. On the other hand, if a difference was detected, the final dataset was limited to data for the mainstem mark groups only.
4. Off-channel mark groups were also rejected if when compared to the estimate using only the mainstem mark group, the estimate using both mainstem and off-channel mark groups was either 1) less precise or 2) differed by more than the standard error of either estimate.

### 5.1.1.4 Population estimates

For the three off-channel sites where full-span weirs were operated, in the absence of evidence to the contrary, we assumed a capture efficiency of $100 \%$ for each weir, and used the total number of smolts captured to estimate smolt production.

We estimated the number of smolts passing each RST on the mainstem of the Coquitlam River using one or more analytical approaches that all rely on a two-sample mark-recapture method. In this study, smolts captured and marked at the weirs or upstream RSTs constituted the marking sample and smolts recovered at an RST represent the recovery sample. With stratified mark-recapture methodology, both the marking and recovery samples are stratified.

## 6. Smolt and Fry Outmigration

## Darroch Maximum Likelihood Estimator

For 2000-2017, we used the maximum likelihood (ML) model developed by Darroch (1961) and modified by Plante (1990) for stratified mark-recapture data. We refer to this model as the Darroch ML model. Darroch ML population estimates and confidence intervals were computed using a software package that is available to the public (SPAS, http//www.cs.umanitoba.ca/ $\sim$ popan/). A description of the ML estimator and the use of the SPAS software is provided by Arnason et al. (1996). In general, we delineated six marking and recovery periods although in some cases, it was necessary to pool strata to avoid small sample and numeric problems that may have prevented the maximum likelihood iterations from converging. When pooling strata, we followed the recommendations of Arnason et al. (1996). When there were no recaptures in a recovery stratum, it was dropped rather than pooled (Schwarz and Taylor 1998).

## Bayesian Time Stratified Petersen Analysis System

In 2018, we started using a Bayesian spline model using the package BTSPAS (Bayesian Time Stratified Petersen Analysis System) developed by Bonner and Schwarz (2014), which was run in the R statistical programming environment (R Core Team 2016). The model was configured for non-diagonal data since marked smolts are often recaptured in the strata they were marked in as well as the next strata. The method has two main components, 1) modeling the general shape of abundance during outmigration using a spline and 2) using a hierarchical Bayesian model that can share capture probabilities (capture efficiency) across strata. BTSPAS is similar to the Darroch ML estimator but can deal with several commonly encountered data problems. First, it helps reduce problems from low numbers of recaptures in some temporal strata by "sharing" capture efficiency information among adjacent strata. Second, the model automatically adjusts the amount it "shares" mark-recapture data between strata based on the amount they vary across periods. It will share capture efficiency data when it is similar (analogous to pooling) but when it isn't, it estimates realistic precision when variation is high. Third, it can interpolate capture rates for strata with missing or minimal mark-recapture data or for strata with missing unmarked fish data.

The model assumes continuous operation of the recapture trap within a stratum. In cases where the recapture trap operates in only a portion of the stratum, the heterogeneity in capture efficiency within the strata is not properly incorporated into the model, leading to overly optimistic estimates of precision as well as bias. Instead, these strata must be flagged as problematic so the data is treated as missing and abundance imputed based on the spline.

Each of the three MCMC chains was run for 20,000 iterations. The first 10,000 were discarded and the remainder thinned at a ratio of 1:50. This provided 6,000 iterations for each estimate.

Model fit was assessed using Bayesian p-values to quantify the similarity between expected and observed recaptures, unmarked captures and both combined. Values close to 0.5 reflect good fit. Values near 0 or 1 indicate potential problems. These values are based on the discrepancy between observed and expected data using either Freeman-Tukey (Freeman-Tukey 1950) or deviance statistics (Schwarz et al. 2009). Second, we checked for model convergence

## 6. Smolt and Fry Outmigration

using the Brooks-Rubin-Gelman statistic (BRG, Brooks and Gelman (1998). Values close to 1, or less than 1.2 were considered adequate.

The present version of BTSPAS does not account for incomplete sampling in capture efficiency estimates. This can lead to biased estimates depending on whether a) incomplete sampling occurred at both the marking and recapture site, b) the marked fraction was constant within each strata and c) marking or recapture was impacted by the incomplete sampling (Schwarz pers.com.). It is possible to "adjust" the number of marked, recaptured or unmarked fish under some circumstances to generate unbiased results. However, precision would be biased high in such situations since the uncertainty from any adjustments are not incorporated into the model. Details of when and how this was done are included in section 5.2. Uncertainty is incorporated into the estimate for strata with incomplete sampling only by excluding all recaptured and unmarked fish within the strata, leaving abundance to be imputed based on the spline.

## Pooled Peterson Estimator

For the years or RST sites with inadequate numbers of marked or recaptured fish to use the Darroch ML model, we used the pooled Peterson Estimator (PPE) for a point estimates of abundance but without confidence intervals. Estimates using the PPE are often biased when capture efficiency varies through the survey period as has often been the case (Arnason et al. 1996) and generally overestimates the precision of the estimate (Schwarz et al. 2009).

## Reach Level Abundance

To estimate smolt abundance originating in each mainstem reach ( $\mathrm{N}_{\text {reach }}$ ), we computed an estimate of mainstem smolts passing a RST at the downstream end of that reach, and then subtracted from this the estimate for the next RST upstream:

$$
\begin{align*}
& N_{\text {reach } 2}=N_{R S T 2}-N_{R S T 3}  \tag{5.5}\\
& N_{\text {reach } 3}=N_{R S T 3}-N_{R S T 4}  \tag{5.6}\\
& N_{\text {reach } 4}=N_{R S T 4} \tag{5.7}
\end{align*}
$$

where $\mathrm{N}_{\text {reach } i}$ was the estimated abundance from reach $i$ and $\mathrm{NRST}_{\mathrm{RS}}$, represents the estimated number of mainstem fish passing an RST site. Note: due to the catch data input into the Darroch ML estimator, NRSTi is estimated directly. However, BTSPAS generates estimates of both the total number of smolts ( $\mathrm{N}_{\mathrm{RST}}$ ) and unmarked smolts ( $\mathrm{URST}_{\mathrm{R}}$ ). With BTSPAS, we used the estimated the number of unmarked fish passing each RST (URSTi) and then added the number of fish marked (M) upstream minus any marked mortalities (m) to estimate the total number of mainstem fish passing the RST (NRSTi). Both approaches result in the same
6. Smolt and Fry Outmigration
estimate of N but including or not including marked fish in N is simplified with the latter approach. Note that when smolts are marked, transported upstream and released, they are not included in N for the trap where they were marked. Marked fish (M) are added to U for each trapping location as follows:

$$
\begin{align*}
& N_{R S T 2}=U_{R S T 2}+M_{R S T 3}+M_{R S T 4}-\left(m_{R S T 3}+m_{R S T 4}\right)  \tag{5.8}\\
& N_{R S T 3}=U_{R S T 3}+M_{R S T 4}-m_{R S T 4}  \tag{5.9}\\
& N_{R S T 4}=U_{R S T 4} \tag{5.10}
\end{align*}
$$

The key to estimating the abundance of smolts only originating from the Coquitlam River mainstem was that all off-channel smolts were marked, thus allowing them to be distinguished from mainstem smolts. Therefore, we assume that all unmarked smolts captured at mainstem sites are mainstem origin fish.

To compute $95 \%$ confidence intervals for $\mathrm{N}_{\text {reach }} 2$ and $\mathrm{N}_{\text {reach }}$ 3, we summed variances for all relevant upstream RST or minnow-trapping mark-recapture estimates. For example, the $95 \%$ confidence interval for smolt estimates for reach 2 would be:

$$
\begin{equation*}
\pm 95 \% C I\left(N_{\text {reach } 2}\right)= \pm 1.96 \sqrt{\operatorname{Var}\left(N_{R S T 2}\right)+\operatorname{Var}\left(N_{R S T 3}\right)} \tag{5.11}
\end{equation*}
$$

Since reach 4 is the uppermost reach, the variance of population estimates is not affected by the uncertainty of mark-recapture estimates for trapping sites upstream:

$$
\begin{equation*}
\pm 95 \% C I\left(N_{\text {reach } 4}\right)= \pm 1.96 \sqrt{\operatorname{Var}\left(N_{R S T 4}\right)} \tag{5.12}
\end{equation*}
$$

Coho and Steelhead smolt production for the Coquitlam River mainstem upstream of RST2 is simply $\mathrm{N}_{\mathrm{RST}} 2$ with a $95 \%$ confidence interval of:

$$
\begin{equation*}
\pm 95 \% \text { CI }\left(N_{\text {mainstem }}\right)= \pm 1.96 \sqrt{\operatorname{Var}\left(N_{R S T 2}\right)} \tag{5.13}
\end{equation*}
$$

The estimate for total smolt numbers for the Coquitlam River study area upstream of RST2 including the four off-channel sites was computed as:

$$
\begin{equation*}
\mathrm{N}_{\text {total }}=\mathrm{N}_{\mathrm{RST} 2}+\mathrm{N}_{\text {Off-channel }} \tag{5.14}
\end{equation*}
$$

with a 95\% confidence interval of:

$$
\begin{equation*}
\pm 95 \% C I\left(N_{\text {total }}\right)= \pm 1.96 \sqrt{\operatorname{Var}\left(N_{R S T 2}\right)} \tag{5.15}
\end{equation*}
$$

6. Smolt and Fry Outmigration

### 5.1.1.5 Mark-recapture assumptions

We evaluated the assumption of population closure by plotting a frequency histogram of daily smolt catches for each weir or RST and then comparing the numbers of smolts captured at the beginning and end of the trapping period to captures during the peak of the migration. Very low catches at the tails of the trapping period relative to catches during the peak were taken as an indication that most smolts emigrated during the trapping period. We assumed $100 \%$ mark retention and $0 \%$ marking-induced mortality based on two earlier studies using similar marking procedures (Decker 1998; Decker and Lewis 1999). With respect to the assumption of equal capture efficiency for marked and unmarked smolts, we assumed marking did not change capture efficiency at the RSTs, but we did not test this directly. To do so would require that there be more than one potential recapture event for individual fish with similar effort for each trapping period (Seber 1982). In our study, individual fish may be recaptured at more than one RST site, but trapping effort is not equal among sites because the efficiency of each RST depends on its location. The steps taken to address potential differences in capture efficiency between marked and unmarked smolts are described in section 5.1.1.3. With respect to the assumptions of constant capture efficiency and proportions of marked to unmarked smolts over time, the use of a stratified mark-recapture design minimizes or avoids violations of these two assumptions by stratifying both the marking and recovery periods. We limited the time period during which capture efficiency and the proportion of marked to unmarked smolts were assumed to be constant within each weekly stratum (Appendix 5.1).

### 5.1.2 Chum and Pink fry enumeration

### 5.1.2.1 Downstream trapping

To estimate Chum and Pink fry out-migrant numbers, we relied on similar methodology to that employed by Cope (2002) on the nearby Alouette River. Prior to 2008 we used two incline plane traps (IPTs) to capture Chum and Pink fry. Beginning in 2008, a 1.3 m diameter RST was used in place of the IPTs (two RSTs were used in 2009). The substitution of an RST for the IPTs reduced cleaning and maintenance demands as well as fish mortality. The RST targeting Chum was operated in reach 2 at the same location as the two RSTs used to trap Coho and Steelhead smolts (RST2 site; Figure 5.1). The main difference between fry and smolt traps is that fry traps use a smaller screening that smolt traps ( 2.5 mm versus 12 mm , respectively).

### 5.1.2.2 Differential marking over time

To generate temporally stratified mark-recapture estimates, the trapping season was divided into weekly strata. Each week, catches of fry from 1-2 days were marked and released immediately downstream of RST3, approximately 3.2 km upstream of the RST2 trapping site. Releases were limited to the first half of the week to allow sufficient time for marked fish to pass the RST2 prior to the end of each week. Thus, all recaptures are assumed to occur within the stratum they are released in. This provided temporally stratified data without the need for different marks. This differed from the approach taken for Coho and Steelhead smolts in that marking was not continuous across all days and recaptures occurred over several subsequent strata.

We mass-marked fry by placing them in a solution of Bismark brown Y, a vital stain (Deacon 1963), and water (1:100,000 concentration) for one hour. Adequate oxygen levels within the solution were maintained using bottled oxygen and a flow meter. Fry were held in a live box and released at dusk to reduce predation. Mortalities prior to release were noted and subtracted from the count for each mark group. Mark loss was not assessed, but Deacon (1963) suggests that fry marked with Bismark brown are readily identifiable for at least 5 days following staining, which agreed with our own observations. Daily captures of Chum were individually sorted from other species (Coho, Chinook and Steelhead), counted and inspected for marks.

### 5.1.2.3 Population estimates

The population estimate and $95 \%$ confidence interval for Chum passing the RST2 site was computed using the same methodology as that for Coho and Steelhead (i.e., NrST2; see section 5.1.1.4). This included the Darroch ML estimator for 2000-2018 and BTSPAS for 20182020 only (see section 5.1.1.4). The estimation process for Darroch ML and BTSPAS is simplified for Chum and Pink fry since all recaptures occur within the marking strata owing to the typically 1-2 days for marked fry to pass RST2. This is referred to as diagonal captures.

Appendix 5.2 Summary of estimated numbers of Coho, Steelhead and Chum smolts passing the three RST trapping locations (not reach estimates) in the Coquitlam River mainstem in 2020. Mark group indicates the location where fish were initially captured and marked. Also shown are numbers of marked (M), recaptured (R) smolts, unmarked captures ( U ) and estimated capture efficiencies ( $\mathrm{R} / \mathrm{M}$ ).

|  | Mark |  |  |  | Capture <br> Species |  |  |  |  |  |  | Site | group(s) | M | R | U | efficiency | mainstem <br> smolts | CI (+/-) | CI (\%) |

Appendix 5.4 Estimated of the number of Coho and Steelhead smolts outmigrating from reaches 2-4 of the Coquitlam River 1996-2020. Individual estimates for four constructed off-channel habitats and mainstem reaches 2-4, both individually and combined, which extends 7.5 km downstream from the Coquitlam Dam.

Appendix 5.5 Age-fork length relationships for Steelhead parr and smolts in the Coquitlam River during 2005-2020 derived from scale-aging analysis.

Appendix 5.6 Mark-recapture data used to test whether the capture efficiency differed between smolts marked using VIE or fin clips for Coho and Steelhead captures at RST 2 during strata 8 and 9 in 2018. Proportions recaptured are considered unaffected by marking method with p values greater than 0.05 .

### 10.5 Appendices for Chapter 6

Appendix 6.1 Criteria used to consider data sets from other rivers suitable for assessing whether abundance changes between treatment periods on the Coquitlam River occurred elsewhere, which would suggest that flow treatment alone was not the only cause of the abundance change.

Control streams were considered based on proximity to the Coquitlam, consistent flow regulation during Coquitlam monitoring period, and the availability of at least three abundance estimates per treatment period. We then compared abundance trends in the Coquitlam to each of the control streams for the years 2000-2009. We used this time period to test the correlation since the primary expectation is that Coquitlam and control streams are comparable prior to the application of the treatment (Treatment 2 flows) even though trends may continue afterwards. Only those with a correlation coefficient $\geq 0.5$ were included from the analysis. Three streams met the criteria: Alouette $R$. $(R=0.75)$, Keogh R. $(R=0.62)$ and Sakinaw Cr. $(R=0.60$, Appendix 6.4). We then completed the BACI analysis using the mean relative change of the three control streams, the Alouette River individually, and the Keogh and Sakinaw combined. We included the Alouette River analysis since we consider this the most similar monitored watershed in terms of watershed size, location, geomorphology, fish assemblage and abundance trends. We included the analysis using the Keogh and Sakinaw due to concerns about the amount of bias between the pre- and post 2008 estimates for the Alouette.

Appendix 6.2 References for annual smolt estimates considered for use as controls steams in the BACI analysis for treatment effects for Coho and Steelhead.

6. Smolt and Fry Outmigration

Appendix 6.4b Annual survival estimates between several starting and ending life stages for Coho, Chum and Pink Salmon and Steelhead Trout in the Coquitlam River. Egg-tosmolt survival estimates are based on adult escapement upstream of the lowermost smolt trapping site (RST2). Unlike Table 6.4a, year corresponds to the adult return year (brood year), as opposed to the year when the juvenile life stage was present. For survival rates among the juvenile life stages of Steelhead (e.g., fry to age $1+$ parr), year corresponds to the younger life stage. Biased-high survival rate estimates (i.e., $>100 \%$ ) are shown in red (see Section 6.2).

|  | Survival by |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |

${ }^{1}$ Assuming a $1: 1$ sex ratio for all species and average fecundity values of 3,200 , 1,800, 3000, and 3,700 eggs/female for Chum, Pink, Coho, and Steelhead; respectively (Groot and Margolis 1991; Ward and Slaney 1993).
${ }^{2}$ Derived from yield of age-2 and age- 3 smolts in subsequent years (see Section 5.2.2.2).

## 6. Smolt and Fry Outmigration

Appendix 6.5 The Pearson correlation coefficient and the sample size ( N ) for the comparison between Coho smolt abundance in the Coquitlam River mainstem and the streams considered as controls for regional changes in freshwater productivity in the Before-After-Control-Impact (BACI) analysis. The comparison included the years 2000-2009, which represents cohorts reared entirely or mostly under Treatment 1. We used correlation coefficient value of 0.5 as the minimum value to include a stream in the BACI analysis.

| Stream | Correlation <br> coefficient $(\mathrm{R})$ | N | Included in <br> BACI analysis |
| :---: | :---: | :---: | :---: |
| Alouette R | 0.75 | 9 | TRUE |
| Keogh | 0.62 | 10 | TRUE |
| Sakinaw Cr | 0.60 | 7 | TRUE |
| Black Cr | 0.38 | 10 | FALSE |
| Cherry Cr | 0.36 | 10 | FALSE |
| Carnation Cr | 0.14 | 10 | FALSE |
| Green River | -0.04 | 7 | FALSE |

Appendix 6.6 Covariates used for Coho adult-to-fall fry Ricker stock-recruitment analysis. All flow metrics based on average 15 minute or hourly discharge for Coquitlam River at Port Coquitlam (Water Survey of Canada, stn. 08MH002). Covariates were transformed to standard deviations with a mean of zero to maintain equal weighting in the model.

| Model \# | Model | Covariate Description |
| :---: | :---: | :---: |
| 0 | NA | none |
| 1 | SPAWN_MEAN | Mean flow: Nov-Jan |
| 2 | INC_MEAN | Mean flow: Feb-Mar |
| 3 | Emerg_MEAN | Mean flow: April-May |
| 4 | SUMMER_MEAN | Mean Flow: June-Sept |
| 5 | WINTER_MEAN | Mean flow: Oct-Feb of rearing winter |
| 6 | WINTER_70 | Days Oct-Feb of rearing winter with discharge > 70 cms |
| 7 | AUG_5.4cms | Days in August with discharge $<5.4 \mathrm{cms}$ |
| 8 | Treatment | Treatment 1 or 2 |
| 9 | Stranded | Number of fry stranded May-July |
| 10 | May_July_diff | Difference in mean flow between May and July |
| 11 | AUG_MEAN | Mean flow in August |
| 12 | SEPT_MEAN | Mean flow in September |
| 13 | OCT_DEC_SD | Standard deviation in flow during Oct-Dec |

Appendix 6.7 Covariates used for Coho adult-to-fall fry stock-recruitment analysis. All flow metrics based on average 15 minute or hourly discharge for Coquitlam River at Port Coquitlam (Water Survey of Canada, stn. 08MH002). Covariates were transformed to standard deviations with a mean of zero to maintain equal weighting in the model.

| Model \# | Model | Covariate Description |
| :---: | :---: | :---: |
| 0 | Base Ricker | none |
| 1 | SPAWN_MEAN | Mean flow: Nov-Jan |
| 2 | INC_MEAN | Mean flow: Feb-Mar |
| 3 | Emerg_MEAN | Mean flow: April-May |
| 4 | SUMMER_MEAN | Mean Flow: June-Sept |
| 5 | WINTER_MEAN | Mean flow: Oct-Feb of rearing winter |
| 6 | WINTER_70 | Days Oct-Feb of rearing winter with discharge > 70cms |
| 7 | AUG_5.4cms | Days in August with discharge $<5.4 \mathrm{cms}(20 \%$ MAD) |
| 8 | Treatment | Treatment 1 or 2 |
| 9 | Stranded | Number of fry stranded May-July |
| 10 | May_July_diff | Difference in mean flow between May and July |

Appendix 6.8 Annual Steelhead smolt abundance during the Treatment 1 and 2 flow period in the Coquitlam River mainstem and the Alouette River. The Alouette River was used as control for regional changes in freshwater productivity.

|  | Treatment <br> Period | Coquitlam <br> Mainstem <br> South Coast BC | Alouette R <br> South Coast BC | Keogh R |
| :---: | :---: | :---: | :---: | :---: |
| Vancouver Island |  |  |  |  |

Appendix 6.9 The Pearson correlation coefficient and the sample size ( N ) for the comparison between Steelhead smolt abundance in the Coquitlam River mainstem and the streams considered as controls for regional changes in freshwater productivity in the Before-After-Control-Impact (BACI) analysis. The comparison included the years 2000-2009, which represents cohorts reared entirely or mostly under pre-Treatment 2 conditions. We used correlation coefficient value of 0.5 as the minimum value to include a stream in the BACI analysis.

|  | Correlation |  | Included in BACI |
| :---: | :---: | :---: | :---: |
| Stream | coefficient (R) | N | analysis |
| Alouette R | 0.521850241 | 9 | TRUE |
| Keogh R | -0.025447947 | 10 | FALSE |

Appendix 6.9 Covariates used for Steelhead adult-to-fall fry stock-recruitment analysis. All flow metrics based on average 15 minute or hourly discharge for Coquitlam River at Port Coquitlam (Water Survey of Canada, stn. 08MH002). Covariates were transformed to standard deviations with a mean of zero to maintain equal weighting in the model.

| Model\# | Model | Covariate |
| :---: | :---: | :---: |
| 1 | Base Ricker | No covariate |
| 2 | Spawning Mean | Mean discharge March-May |
| 3 | Incubation Mean | Mean discharge June-July |
| 4 | June Mean | Mean discharge June |
| 5 | July Mean | Mean discharge July |
| 6 | August Mean | Mean discharge Aug |
| 7 | Difference Spawn Incub | Difference in mean discharge between spawning and incubation |
| 8 | Proportion Aug> 5.4cms | Proportion of days in August above $5.4 \mathrm{cms} \mathrm{(20} \mathrm{\% MAD)}$ |
| 9 | Treatment | Flow Treatment 1 or 2 |

Appendix 6.10 Covariates used for Steelhead fall fry-to-fall parr stock-recruitment analysis. All flow metrics based on average 15 minute or hourly discharge for Coquitlam River at Port Coquitlam (Water Survey of Canada, stn. 08MH002). Covariates were transformed to standard deviations with a mean of zero to maintain equal weighting in the model.

| Model \# | Model | Covariate |
| :---: | :---: | :---: |
| 1 | Base Ricker | No covariate |
| 2 | Proportion Sept> 5.4 cms | Proportion of days in September above 5.4cms (20\%MAD) |
| 3 | Fall Mean | Mean discharge Sept-Oct |
| 4 | Winter Mean | Mean discharge Nov-March |
| 5 | Spring Mean | Mean discharge April-May |
| 6 | Summer Mean | Mean discharge June-Aug |
| 7 | Proportion Aug $>5.4 \mathrm{cms}$ | Proportion of days in August above 5.4cms (20\%MAD) |
| 8 | Winter days $>70 \mathrm{cms}$ | Days Nov-March with discharge $>70 \mathrm{cms}$ |
| 9 | Treatment | Flow Treatment 1 or 2 |

Appendix 6.11 Preliminary ANCOVA results for Chum 2003-2016 brood years to examine the significance of flow treatment on fry yield during Treatment 1 (2000-2008) and Treatment 2 (2009-2020) in the Coquitlam River including the significance of $F$ values. The null hypothesis in all cases is that the predictive variable is not a significant predictor of fry yield. Escapement x Treatment represents the interaction effect that would produce different slopes of the stock-recruitment relationships for Treatment 1 and 2.

| Coefficient | F value | Significance level <br> probablilty $(>\mathrm{F})$ | Null hypothesis prob <br> $<0.05$ |
| :--- | :---: | :---: | :---: |
| Intercept | 327 | $<0.001$ | reject |
| Escapement | 1.24 | 0.27 | do not reject |
| Treatment | 8.03 | 0.013 | reject |
