## EXECUTIVE SUMMARY

A small component of the endangered Columbia White Sturgeon population resides in Arrow Lakes Reservoir (ALR), between Hugh L. Keenleyside (HLK) and Revelstoke (REV) dams. Spawning has been documented intermittently since 1999, primarily in an area approximately 5 km downstream of REV adjacent to the Revelstoke Golf Course. The Columbia River White Sturgeon Management program was initiated to address flow management issues with respect to impacts on White Sturgeon (*Acipenser transmontanus*) spawning events, timing, frequency, egg deposition, and habitat conditions. Monitoring conducted in 2017 was the 11<sup>th</sup> consecutive year of the middle Columbia River White Sturgeon spawning monitoring study program (CLBMON-23A).

White Sturgeon spawn monitoring in the middle Columbia River was conducted between July 19 and September 7, 2017 between river Km 228.0 and 230.3. Effort and methodology were consistent with previous years. Egg mats were inspected weekly for the presence of White Sturgeon eggs and/or free embryos. Drift nets were set weekly during the day (average of 3.0 hours per set) as well as overnight (average of 15.5 hours per set) between July 19 and September 7. In total, 23,263 hours of egg mat sampling effort and 380 hours of drift net sampling effort was expended in 2017. A total of seven White Sturgeon eggs were captured on egg mats and one egg and one free embryo were captured in drift nets.

Discharge from REV reached a peak of 1,899 m<sup>3</sup>/s during the monitoring period, which was lower than the peak discharge observed during this study (2,573 m<sup>3</sup>/s in 2012), but higher than the maximum discharge observed prior to the installation of a fifth unit at REV in late 2010 (1,757 m<sup>3</sup>/s). Backwatering of ALR in the spawning area occurred from June 9 to September 2, throughout the duration of the spawning period in 2017. The current state of knowledge for White Sturgeon spawning below Revelstoke Dam with respect to BC Hydro's management questions for CLBMON-23a is provided below.

Management Question	Status
Where are the primary White Sturgeon incubation sites below Revelstoke Dam?	Based on White Sturgeon spawning studies conducted below Revelstoke Dam since 1999, the primary White Sturgeon incubation area is located within a 2.2 km river section between Km 227.9 and 230.1, which encompasses the area adjacent to the Revelstoke golf course. All 299 eggs and 51 free embryos collected since 1999 have been captured in this area. White Sturgeon eggs have consistently been documented in this relatively small area despite past sampling at other potentially suitable areas between 1 km downstream of Revelstoke Dam (Km 234) and the Illecillewaet River (Km 223.5). Revelstoke Dam is located at Km 235. The boundaries of this small spawning/incubation area may shift slightly depending on flows and ALR elevation, but remains relatively similar between years.
How do dam and reservoir operations affect egg and free embryos survival in this area? Specifically, do significant numbers of eggs become dewatered as a	Estimates of egg or larval survival are difficult to calculate for sturgeon species, even in systems where more data are available. In this program, the ability to estimate survival of early life stages was not possible due to the low number of eggs/larvae that were collected. The effect of reservoir

<p>result of operations?</p>	<p>operations on physical parameters within the REV egg incubation area has been investigated further under CLBMON-54.</p> <p>Minimum flows implemented following the addition of a 5<sup>th</sup> turbine at REV in 2011 have increased the permanently wetted river bed area in the middle Columbia River and reduced the exposure of shallow gravel bars within the egg incubation area to the extent that egg and larval stranding is likely not possible. Stranding surveys were conducted in 2009 and 2011, with eggs located on an exposed gravel bar in 2009 before minimum flows were implemented. While it is not likely that egg and larval stranding in the spawning area below REV is possible under current operations, it would need to be considered for operations during the spawning period (July-september) where flows are less than 142 cms.</p>
<p>What is the most effective method for monitoring spawning of White Sturgeon?</p>	<p>Based on the broadcast spawning of the species, the most effective method for monitoring White Sturgeon spawning in the mid-Columbia River is a combination of egg mats and drift nets. Egg mats sample continuously to collect eggs from spawning adults while drift nets are more efficient in identifying the downstream dispersal of larvae, especially once spawning has been identified and time of hatch has been estimated. During the past 11 years of this program, an average of 125 egg mats have been deployed per spawning season for approximately 21,055 hours which resulted in an average catch-rate of 0.01 eggs/free embryos per hour. In contrast, an average of 38 drift nets have been deployed per spawning season for approximately 197 hours which resulted in an average catch-rate of 0.13 eggs/free embryos per hour. Although drift nets seem to have higher catch-rates, they do not fish continuously like egg mats and may miss downstream dispersal of free embryos after hatch occurs. Seven eggs were captured on egg mats in 2017 while drift nets captured one egg and one free embryo.</p>
<p>Can modifications be made to operation of Revelstoke Dam and Arrow Lakes Reservoir to protect or enhance White Sturgeon incubation habitat?</p>	<p>It is unknown at this time whether additional modifications to REV/ALR operations can be made to protect or enhance White Sturgeon incubation habitat. Flow modifications have already occurred with the addition of REV5. For example, a 142 m<sup>3</sup>/s minimum flow requirement was initiated concurrent with REV5 coming online (December 2010). Preliminary information collected during this monitoring program before and after REV5 suggests that operational modifications may reduce White Sturgeon egg stranding due to an increase in minimum flow. In addition, spawning has been recorded 6 of the 7 years following the addition of REV5.</p>

	<p>The influence of REV operations and ALR elevation on physical conditions observed at the spawning area was also assessed during concurrent BC Hydro WUP programs including: CLBMON-15a (Middle Columbia River Physical Habitat Monitoring), CLBMON-20 (Middle Columbia River White Sturgeon Spawning Habitat Assessment), CLBMON-27 (Middle Columbia River Sturgeon Incubation and Rearing Study) and CLBMON-54 (Middle Columbia River Effects of Flow Changes on Incubation and Early Rearing Sturgeon). Results of these studies related to White Sturgeon incubation habitats are briefly discussed.</p>

## 1 INTRODUCTION

White Sturgeon (*Acipenser transmontanus*) have experienced reduced population abundance in the Canadian portion of the Columbia River due to recruitment failure, altered food resources, and degradation or lack of access to suitable habitats (Porto 2008) and were listed as endangered under federal Species at Risk Act (SARA) legislation in 2006. The Columbia River population has been considered at significant risk of extirpation in the wild given strong evidence that, for several decades, natural recruitment has been too low to sustain this population (Hildebrand and Parsley 2013). While conservation aquaculture is being used to prevent extirpation, research into hypotheses related to recruitment failure is ongoing, including monitoring of spawning adults to describe the timing, frequency, and locations used for spawning.

A small component of the Columbia River population resides in the area between Revelstoke Dam (REV) and Hugh L. Keenleyside Dam (HLK), which includes the Arrow Lakes Reservoir (ALR; Figure 1). This population component, referenced as the mid-Columbia River population, is comprised of approximately 52 adult White Sturgeon (population estimate ranges between 37 - 92 individuals at 95% confidence level) that are older than the 1969 age class (Golder 2006); construction of HLK Dam was completed in 1969. This small segment of the Columbia White Sturgeon population has experienced total recruitment failure (Hildebrand and Parsley 2013) even though natural spawning has been documented downstream of REV, near the Revelstoke Golf Course since 1999 (R.L. & L. Environmental Services Ltd. 2000). Spawning has been intermittent and naturally produced juvenile White Sturgeon have never been captured (Hildebrand and Parsley 2013). Spawning investigations occurred in 1999, 2000, 2001, 2003, 2006 through 2017 with spawning events documented in 1999, 2003, 2006, 2008, 2009, and 2011 through 2017 (Golder 2012a, Amec Foster Wheeler 2017). Spawn timing has been estimated to occur from late July through August and this area represents the only known spawning area for White Sturgeon in the ALR (BC Hydro 2012) and has been designated, under the Species at Risk Act, as Critical Habitat for White Sturgeon by Fisheries & Oceans Canada (2014).

Revelstoke Dam was built in 1984 and its operations are a function of discharges from the Mica Dam and local inflows to Revelstoke reservoir combined with electricity demand. REV is a hydropeaking facility and since early 2011 discharges within a 24 hour period have varied between the operational minimum of 142 m<sup>3</sup>/s to approximately 2100 m<sup>3</sup>/s (BC Hydro 2012, Golder 2012a). Prior to the installation of a fifth turbine unit in December 2010, referred to as 'REV5', flows could be varied from zero to approximately 1700 m<sup>3</sup>/s (Golder 2012a). The effect of hydropeaking operations at REV is a constant variation in flow rates at the White Sturgeon spawning area downstream of the REV tailrace, approximately 5 km from Revelstoke Dam. Further adding to the complex flow regime is a backwatering effect observed as far upstream as REV when ALR water levels exceed 437 meters above sea level, which generally occurs before and during the White Sturgeon spawning period.

BC Hydro and others have funded a number of White Sturgeon investigations in ALR since 1995, which has included spawn monitoring downstream of REV since 1999. Annual spawn monitoring below REV is required under the terms of the Columbia River Project Water Licence (WLR) Order to document spawning events, timing, frequency, egg deposition, and habitat conditions (BC Hydro 2012). Spawn monitoring studies under BC Hydro's WLR

process were carried out from 2007 to 2011 below REV (CLBMON-23A) with concurrent studies that assessed the feasibility of sonar techniques for detecting adult White Sturgeon within the spawning area (CLBMON-23B; as cited in Golder 2012a; Crossman et al. 2011). An additional seven years of spawning investigations were undertaken to document spawning events, timing, frequency and egg deposition to inform future management decisions. Amec Foster Wheeler has been conducting these additional spawning investigations since 2012.

## **1.1 Objectives**

The primary objectives of this monitoring program are to (BC Hydro 2012):

1. Assess sturgeon incubation sites and conditions downstream of Revelstoke Dam;
2. Relate egg stranding risk to discharge from the dam and water elevation of Arrow Reservoir;
3. Assess the feasibility of underwater videography or other remote sensing techniques for monitoring presence of White Sturgeon spawners (already covered under CLBMON-23B);
4. Select and implement the most effective method (egg mats or videography or other remote sensing) for ongoing monitoring of spawning of White Sturgeon (already covered during previous studies conducted under CLBMON-23A and 23B); and
5. Provide input to recommendations for the water allocation schedule for White Sturgeon spawning and incubation.

The Management Questions to be addressed through this study are (BC Hydro 2012):

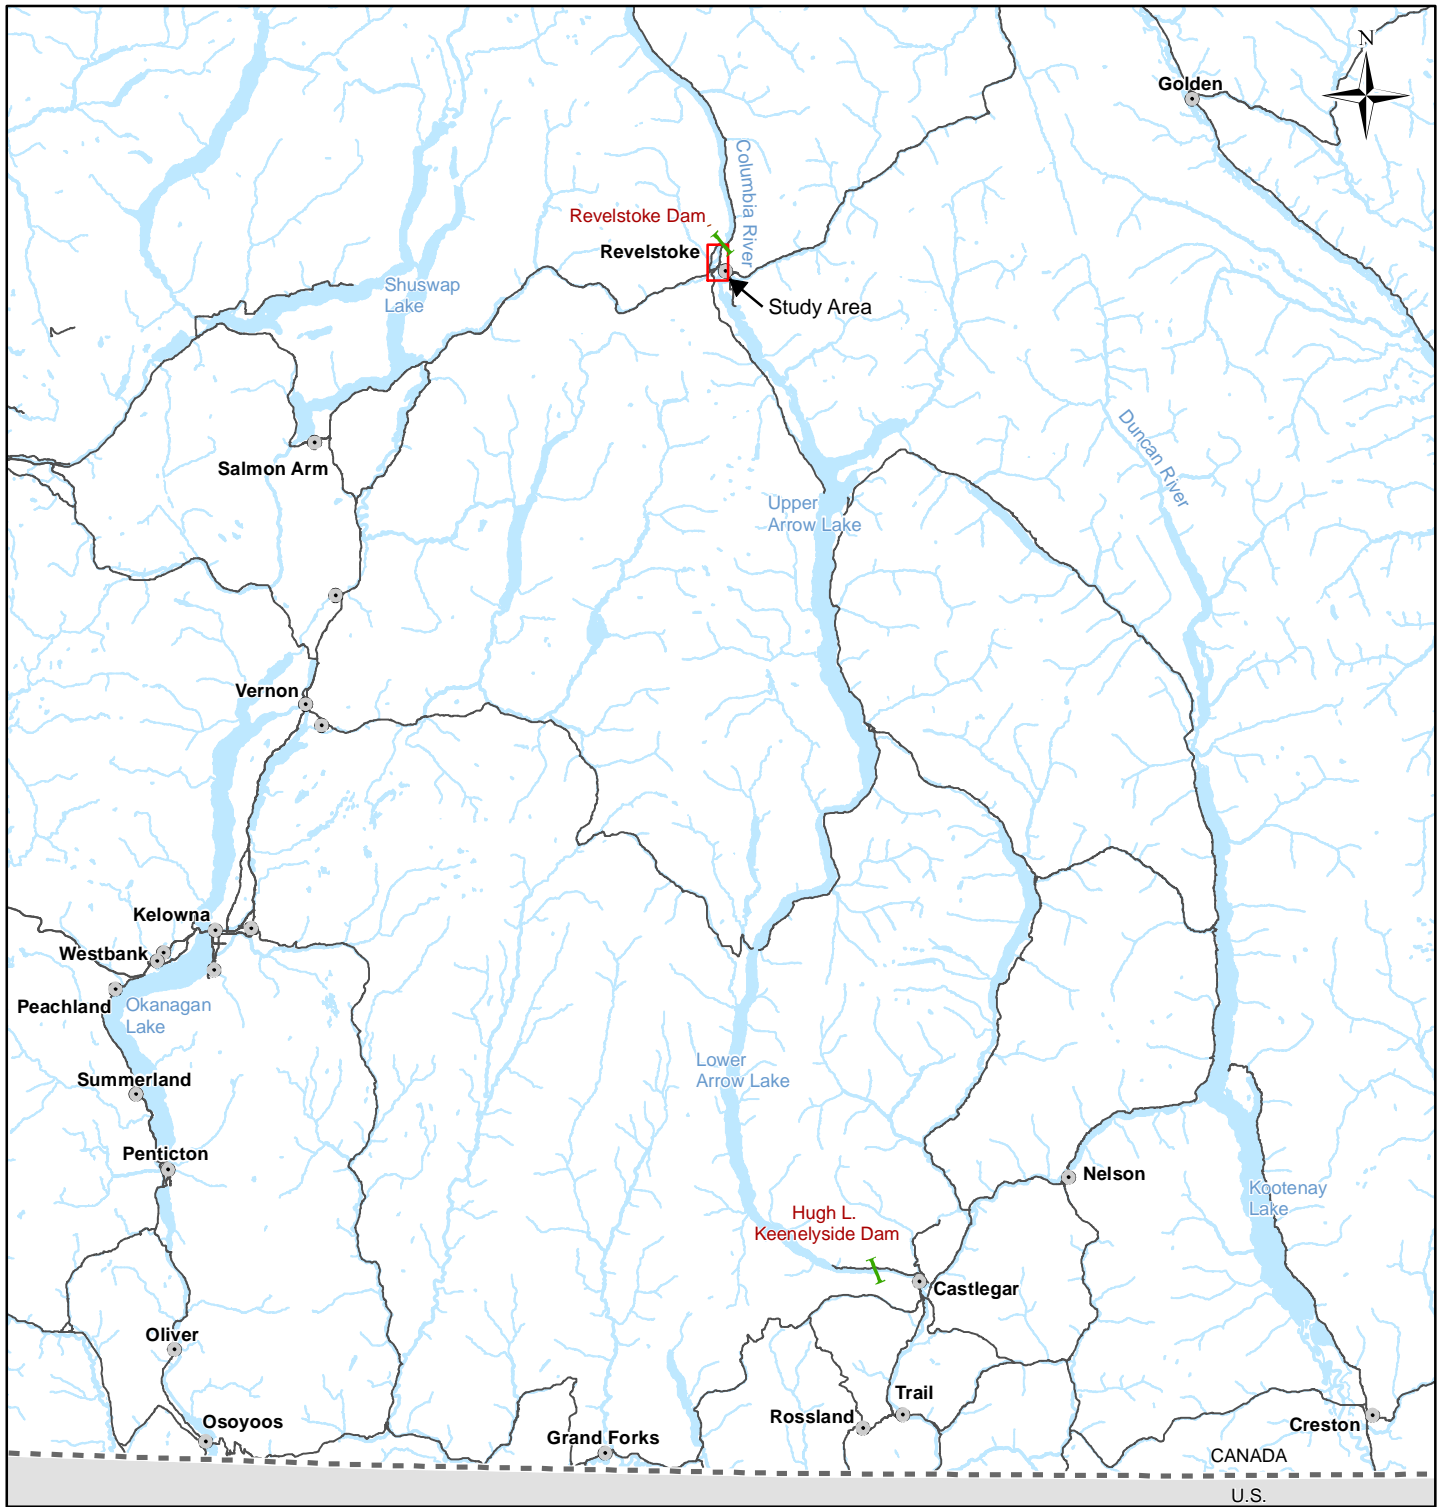

1. Where are the primary White Sturgeon incubation sites below Revelstoke Dam?
2. How do dam and reservoir operations affect egg and larvae/free embryos survival in this area? Specifically, do significant numbers of eggs become dewatered as a result of operations?
3. Can underwater videography or other remote sensing methods be used to effectively monitor staging and spawning of White Sturgeon?<sup>1</sup>
4. What is the most effective method for monitoring spawning of White Sturgeon?
5. Can modifications be made to operation of Revelstoke Dam and Arrow Lakes Reservoir to protect or enhance White Sturgeon incubation habitat?

## **1.2 Purpose**

The following report fulfills Amec Foster Wheeler's commitment to provide BC Hydro with a data report for studies conducted in 2017 and adds to the dataset collected in previous years.

---

<sup>1</sup> This management question was addressed under a different program (CLBMON-23B Mid-Columbia River White Sturgeon underwater videography feasibility study; Johnson et al. 2009) and will not be further addressed by the present program.

## 2 METHODS

### 2.1 Study Area

Since spawn monitoring was initiated in 1999, sampling has been conducted from approximately 1 km downstream of Revelstoke Dam (Km 235) to the mouth of the Illecillewaet River (Km 223.5) (R.L. & L. Environmental Services Ltd. 2001, Golder 2008). Based on the results of egg and larval captures, the sampling area has been continually refined over time to focus on the primary spawning habitats identified. The 2017 study area was concentrated in between Km 227.8 and 230.3 ( Figure 2), which incorporated the area where all White Sturgeon eggs have been captured since 1999 (Golder 2012a, Amec Foster Wheeler 2016).

### 2.2 Environmental Parameters

In order to help answer Management Questions 2 and 4 pertaining to operations and risk of egg dewatering, environmental parameters were monitored during the program. Hourly discharge (m<sup>3</sup>/s) from REV, separated by turbine and spillway flow, and water surface elevation (meters above sea level) of ALR at Nakusp were obtained from BC Hydro Power Records covering a time period of April through September to cover the pre-spawning through incubation period and be consistent with previous reporting. Water temperature (°C) and water surface elevation data collected under CLBMON-15a Middle Columbia River Physical Habitat Modelling at 10 minute intervals were obtained for Station 2 (“Reach 4 downstream”), which is located at river Km 231.1 on the left downstream bank (UTM Zone 11U, Easting 414925, Northing 5653213). A thermograph station, using Onset TidbiT v2 loggers accurate to 0.2°C, was deployed to provide a backup of hourly water temperature data within the spawning area (Km 229.6L; Figure 2).

### 2.3 Sample Timing

Sampling was conducted between July 19 and September 7, 2017 during the documented White Sturgeon spawning period below Revelstoke Dam. A summary of field sample sessions is provided in Table 1.

**Table 1: Sampling effort for CLBMON-23 Middle Columbia River White Sturgeon spawn monitoring, 2017.**

<b>Date</b>	<b>Activities</b>
July 19-20	Deployed ten mid-channel and ten near shore egg mat/drift net sample stations.
July 26-27	Retrieved, checked and redeployed egg mats. Drift net sampling.
August 2-3	Retrieved, checked and redeployed egg mats. Drift net sampling.
August 9-10	Retrieved, checked and redeployed egg mats. Drift net sampling.
August 16-17	Retrieved, checked and redeployed egg mats. Drift net sampling.
August 23-24	Retrieved, checked and redeployed egg mats. Drift net sampling.
August 30-31	Retrieved, checked and redeployed egg mats. Drift net sampling.
September 6-7	Retrieved and checked egg mats. Drift net sampling. Removed sample stations.

## **2.4 Spawn Monitoring**

### **2.4.1 *Egg Collection Mats***

In order to maintain consistency in sampling methods across years, egg mats were used to collect White Sturgeon eggs/free embryos. This method has been successfully used in the middle Columbia River to monitor White Sturgeon spawning (e.g., Golder 2012a, Amec Foster Wheeler 2016) and has been used throughout the Columbia basin in both Canada and the US to monitor other White Sturgeon populations (e.g., McCabe and Beckman 1990).

Discharge from Revelstoke Dam, along with substrate conditions in the area, limit where egg mats can be deployed due to high water velocities (>2 m/s; Golder 2014) that can result in gear displacement. Egg mats were retrieved/deployed from a boat as per BC Hydro's Specific Work Instructions and is described herein. Between 20 and 22 egg mat stations were deployed (half set to shore and the other half anchored middle channel sets) weekly. Mats were deployed between Km 227.8 and 230.3. The number of egg mat stations deployed depended on station displacement and gear availability. Egg mats were also deployed overnight during the two days of weekly sampling when drift nets were not being set overnight at those locations (Section 2.4.2). A combination of nearshore and mid-channel egg mat sets have been used below REV during the past nine years of this program in an attempt to cover potential spawning areas across the river channel. Nearshore sets included stations on both left and right banks of the spawning area, whereas effort prior to 2007 was mainly concentrated along the left downstream bank.

Each egg mat was comprised of a steel frame that enclosed latex covered animal hair filter material. The filter material was present on both sides of the frame, so when deployed, one side of the filter material was always sitting upward where drifting eggs and free embryos could lodge and attach. Egg mat dimensions were approximately 0.77 m by 0.92 m.

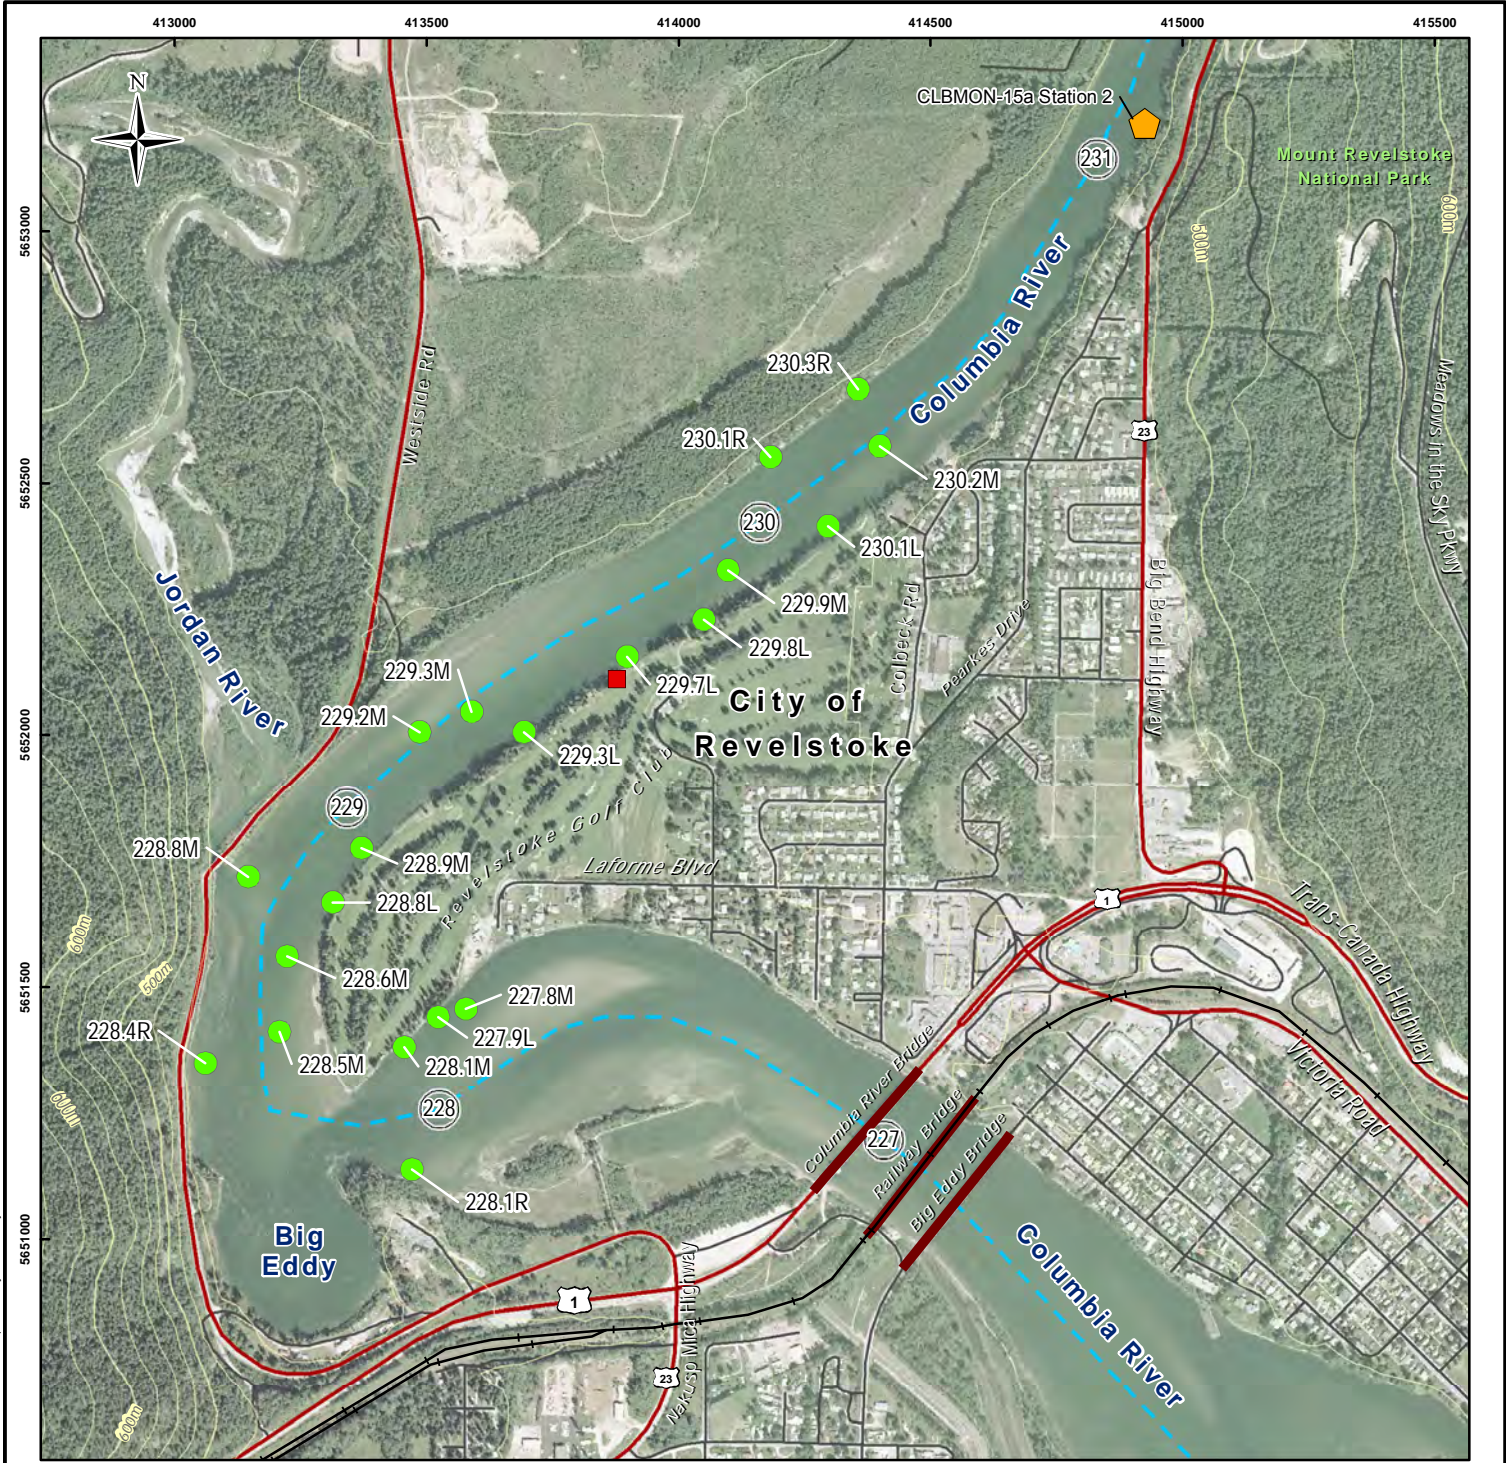

The egg mat system consisted of two 30 kg claw anchors attached to one another with an approximately 6 m galvanized steel chain and a float line which attached to the front anchor; a 10 m rope attached the rear anchor to the egg mat with a second float line (15 to 45 m) coming off the rear of the egg mat for retrieval. The lengths of rope used depended on depth and degree of flow fluctuations that were encountered.

Egg mats had a rope bridle system attached to each end, so that one end was attached to the rope/chain/anchor and the other bridle had a separate float line for retrieval. The retrieval float line was pulled up by the field crew, wrapped around the winch of the boat (which was permanently affixed to the bow) and used to pull the egg mat up. The egg mat was detached from the rope system and a spare egg mat was attached to the rope system and deployed. The boat operator drove to the shore and the field crew inspected the egg mat. Near shore egg mat sample locations were tied to shore instead of having a second float line. Having two float lines on mid-channel sets allowed the field crew to pull up the egg mat directly, but also the float line attached to the anchor provided a secondary means to pull up the egg mat set, should there have been a problem with the egg mat float line.

Data collected at each egg mat included: station name (e.g., J30 = retrieval buoy labelled J30); UTM; channel location (L= left bank when facing downstream, R = right bank and M = mid-channel); set and pull date and time; water temperature; set depth; number of eggs;

number of free embryos; number of eggs/free embryos preserved; other species/observations; and, any relevant comments. If egg mats drifted significantly, they were moved back to their original location and noted in the comments; no new site designation was required. Data was recorded on standard data sheets set up for this program (see AMEC 2013). A photograph of each data sheet was taken during each field session to provide a backup. In the office, all data sheets were additionally scanned and then entered into MS Excel. GIS was used to convert each site UTM collected in the field to a river kilometre with channel location designation (e.g. 229.0L = river Km 229.0; L = left downstream bank). QA/QC was completed by a separate person who checked entered data for errors by comparing to field data sheets. The locations of egg mat stations are provided (Figure 2). Catch-per-unit effort (CPUE) was calculated for each egg mat (number of White Sturgeon eggs/hour of effort) for comparison between sampling locations and years (Appendix A).

#### 2.4.2 *Drift Nets*

Previous studies have determined that the most effective method for monitoring White Sturgeon spawning in the study area (Management Question 4) is a combination of egg mat and drift net sampling (Golder 2012a, Amec Foster Wheeler 2016). Accordingly, White Sturgeon eggs/free embryos were collected using drift net sampling (referred hereafter as drift nets). This method has been successfully used to collect White Sturgeon eggs/free embryos in the middle and lower Columbia rivers in Canada as well as throughout the Columbia River in the US. Drift nets consist of a D-shaped metal frame (0.8 m wide by 0.6 m high) with an attached net (3.6 m long, 0.16 cm knotless mesh, 11.4 cm diameter collection bottle). In addition, a flow meter (e.g., General Oceanics) was fixed to the D-ring frame at the top of the opening to measure the volume of water sampled; this method has been used during the past eight years for drift net sampling in the middle Columbia River.

Drift net sites were selected to cover the upper, middle and lower portion of the spawn monitoring area during each field survey. A minimum of two and maximum of ten drift net sets were deployed weekly and concentrated in the spawning area between Km 227.8 and 230.1. Drift nets used egg mat anchor and shoreline sites established during the first field session, with site 227.9L used as a consistent weekly set and other sites used over the study period to distribute effort to additional potential deposition areas. Egg mat sites were removed on the first sampling day, checked for eggs/free embryos and replaced with drift nets. Drift nets were removed after 2.5 to 3.6 hours (depending on time available) and replaced with egg mats which soaked overnight or remained for a week, depending if the site was to be resampled the following day. This was repeated on the second sampling day but once drift nets were pulled the egg mat remained in situ for a week. Therefore, drift nets were set on two consecutive days per week within the study area as per the past eight years of study in the middle Columbia River. In 2012, drift nets were only set during the first sample day and overnight sets were not possible due to higher water levels than experienced during this program in the past (AMEC 2013). However, conditions in years since have permitted the use of overnight sets (i.e. gear was able to withstand overnight debris loading). In 2017, two to three drift nets were set overnight once per week July 26 through September 6. Overnight drift nets sampled for 14-16 hours from late afternoon until the next morning.

Two 30 kg claw anchors were used for drift net sites. Anchors had approximately 6 m of galvanized steel chain between them. The first anchor had a float line attached and the second anchor had a section of chain then rope to attach the drift net. The bottom end of the drift net frame was clipped onto this chain/rope line. The drift net was weighted at the front corners (approximately 4.5 kg lead weight attached to each corner) to ensure it remained upright in the water in order to more effectively sample drifting debris/aquatic life (e.g., Howell and McLellan 2006 as cited in Golder 2012a; personal observations). A second float line for retrieval was attached to the top of the drift net frame. Retrieval of the drift net was similar to the egg mat in that the float line was retrieved and the winch used to pull the drift net into the boat. The drift net was detached and the float line reattached. Drift nets were set on the same anchor systems and/or rope used for egg mat sampling (Section 2.4.1). Upon retrieval of the drift nets, the contents of the bottle and drift net were emptied into a white bucket. The contents of the bucket were further diluted with river water into small white wash

basins and field crew members sorted through the debris to find and collect any White Sturgeon eggs/free embryos using tweezers.

Data recorded for drift net sampling included: station name (similar to egg mats); river km and channel location; set and pull date and time; water temperature; set depth; start/end readings of the flow meter for calculation of water volume sampled; number of eggs/ free embryos; number preserved; other species observed; and, relevant comments (e.g., drifting of station, quantity of debris, whether eggs/free embryos were alive/dead). Data recording, entry and QA/QC followed that outlined for egg mats above. Locations for drift nets are provided in Figure 2. Catch-per-unit effort (CPUE) was calculated for each drift net (number of White Sturgeon/hour and number/100 m<sup>3</sup> water volume) for comparison with other sampling years.

## **2.5 Egg Incubation, Staging & Spawn Timing Estimation**

The following are standard egg processing methods used during this program. White Sturgeon eggs were immediately staged on the boat upon capture. Standard egg staging procedures were used as described in Jay et al. (2016), Dettlaff et al. (1993) and Wang et al. (1985). If this was not possible, eggs were preserved in Prefer and staged by dissection microscope in the office. Eggs staged in the field were placed in incubation trays that were anchored in the river in a location close to the point of capture. Eggs were incubated *in situ* until hatch. Incubation trays consisted of flat plastic trays with wells for approximately 100 individual eggs covered by a top plate. All free embryos, including those hatched in incubation trays as well as those collected in drift nets, were preserved in 90% ethanol to be used in future genetic analyses (e.g. parentage assignment; Jay et al. 2014).

Egg and free embryo stages were used with mean water temperatures observed during sampling to estimate the number and timing of spawning events based on developed relationships (Parsley et al. 2011; Wang et al. 1985). The total number of eggs/free embryos, status (alive/dead/damaged), spawn timing and number of estimated spawning events were summarized. In the case of any free embryo stages falling between those noted by Wang et al. 1985, a range was calculated to cover the possible spawn timing.

## **2.6 Egg Stranding**

In order to address Management Question 2 egg stranding surveys were to be conducted when White Sturgeon spawning event(s) were detected, depending on water levels. White Sturgeon eggs have been previously observed to dewater at a cobble/gravel bar across from the mouth of the Jordan River (~Km 228; Figure 2).

## **2.7 Sampling Effort Maps**

Maps were created to illustrate total effort by 500 m river section from Km 235 (Revelstoke Dam) to Km 223.5 (downstream of the Illecillewaet River). One version of this map was created using data collected between 2012 and 2017 that compiled the total combined egg mat and drift net sampling hours expended in each river section and identified the locations where eggs and/or free embryos were captured during that period. A second version was created identifying how many years of sampling has occurred in each river section between 1999 and 2017 and identified the locations where eggs and/or free embryos have been captured over the duration of the entire program.

### 3 RESULTS

#### 3.1 Environmental Parameters –Elevation, Discharge and Temperature

Arrow Lake Reservoir elevation steadily increased between April and July, reaching a peak elevation of 439.5 m above sea level (masl) in late-July and gradually decreased through the remaining study period (Figure 3). Surface elevation at Nakusp above 437 masl backwaters ALR to the spawning area (Golder 2011). ALR reached this elevation between June 9 and September 2 in 2017; therefore ARL was backwatering the spawning area throughout the entire spawning period in 2017 (Figure 3).

**Figure 3:** Hourly discharge ( $m^3/s$ ) from Revelstoke Dam (REV) and hourly water level elevation (meters above sea level) of Arrow Lakes Reservoir (ALR) as measured in Nakusp, BC, April 1 to September 30, 2017. The black dotted line represents 437 masl elevation when ALR backwaters the spawning area.

Water level elevation over the spawning area reached its summer maximum during early July with the highest elevation of 441.3 masl (as measured at CLBMON-15a Station 2 level

logger at Km 231.1) on August 8 at 17:00 (Figure 4). Minimum elevation of 438.1 masl was observed on September 4 at 05:00 (Figure 4). Daily fluctuations in elevation ranged between 0.2 and 2.9 m/day for the duration of the study period (Figure 4). Water elevation at the spawning area followed the discharge release pattern from REV over the duration of the study period (Figure 4).

**Figure 4:** Hourly total discharge (m<sup>3</sup>/s) from Revelstoke Dam (REV) and hourly water surface elevation (meters above sea level) measured at CLBMON-15a Station 2 at Km 227.8, July 1 to September 30, 2017.

Discharge from Revelstoke Dam exhibited daily fluctuations due to the hydropeaking operations at the facility (Figure 3). Peak discharge during the sturgeon spawning period was observed in mid-August (1899 m<sup>3</sup>/s on August 11 at 0:00) (Figure 5). Discharge did not drop below 254 m<sup>3</sup>/s between July and September 2017 (Figure 5). Spill gates were used sporadically March through June, but not during the spawning period in 2017 (unpublished data, BC Hydro Power Records, 2017).

Water temperatures at the spawning area are the result of a combination of thermal conditions in the REV forebay, REV discharge volume and the presence or absence of a backwater effect from ALR (Golder 2011). During the 2017 spawning monitoring study period, water temperature fluctuated between 8.5°C and 13.4°C (Figure 5).

**Figure 5:** Hourly total discharge (m<sup>3</sup>/s) from Revelstoke Dam and hourly water temperature (°C) measured at CLBMON-15a Station 2 at Km 227.8, July 1 to September 30, 2017.

### **3.2 White Sturgeon Egg & Free Embryo Collection**

#### **3.2.1 *Egg Collection Mats***

Seven White Sturgeon eggs were collected on egg mats in 2017 (Table 2; Appendix A). No free embryos were collected on egg mats in 2017. In total, 23,263 mat-hours of effort (mean sample duration per egg mat = 163 hours; SD = 24.7) were spent during the 2017 sampling period (Table 2 and Table 3; Appendix A). A summary of effort by year (2007-2017) and sampling method is provided in Table 3.

**Table 2: Summary of egg collection mat sampling, July 19 to September 7, 2017.**

<sup>a</sup> CPUE for egg mats = captures/24 mat-hours; CPUE for drift nets = captures/hour

### 3.2.2 Drift Nets

One White Sturgeon egg and one free embryo were captured by drift nets in 2017 (Table 4; Appendix B). Drift nets were set during the day (n=50) for a total of 141 hours (mean sample duration = 2.8 hours; SD = 0.3) and overnight (n=16) for a total of 239 hours (mean sample duration = 14.9 hours; SD = 0.4; Appendix B). Total water volume sampled during daytime

drift net sets was 102,967 m<sup>3</sup>, the mean water volume per daytime drift net set was 2,145 m<sup>3</sup> (SD = 2,144) and velocity was 42.1 cm/s (SD = 43.3; Appendix B). Volume and velocity measurements were not analyzed for overnight sets as the instruments potentially reset themselves over the duration of the set. A summary of sample effort by year and sampling method is provided in Table 3.

**Table 4: Summary of drift net sampling, July 19 to September 7, 2017.**

Notes: <sup>a</sup> Does not include volume of overnight drift net sets as meters zero'ed themselves an unknown number of times.

### 3.3 Egg Incubation

Four of the eggs collected on July 26, 2017 were incubated at Km 229.1L. Upon inspection the following week (August 3) the eggs had hatched. Another egg was collected on August 2, 2017 and hatched later that day. These free embryos were collected and preserved in ethanol for future analysis, as was the one free embryo collected on August 10, 2017 (Table 5). Between 2012 and 2017, three viable eggs, 18 dead eggs and 36 free embryos were preserved for future genetic analysis.

### 3.4 Staging & Estimated Spawn Timing

Based on egg stages and water temperatures, one spawning event occurred on July 21, 2017. The date of spawn timing was determined based on egg stage when captured on July 26 (stage 26) and average water temperature (10°C) over the previous 5 days (

Table 5). Wang et al. (1985) found eggs at this stage and water temperature were fertilized 118 hours prior suggesting spawning occurred at approximately 17:00 on July 21, 2017.

A second egg was captured at the same location the following week, on August 2 (stage 35). Water temperature over the previous 10 days was approximately 10°C suggesting fertilization occurred approximately 256 hours and spawning occurred at 11:30 on July 22, 2017. However, cool thermal regimes such as the middle Columbia River have been found to slow egg development (Parsley et al. 2011), temperature fluctuations occurred during the incubation period making exact spawning date determinations of later

staged eggs less reliable (Wang et al. 1985) and it is very likely this egg was spawned during the same event as eggs collected July 26.

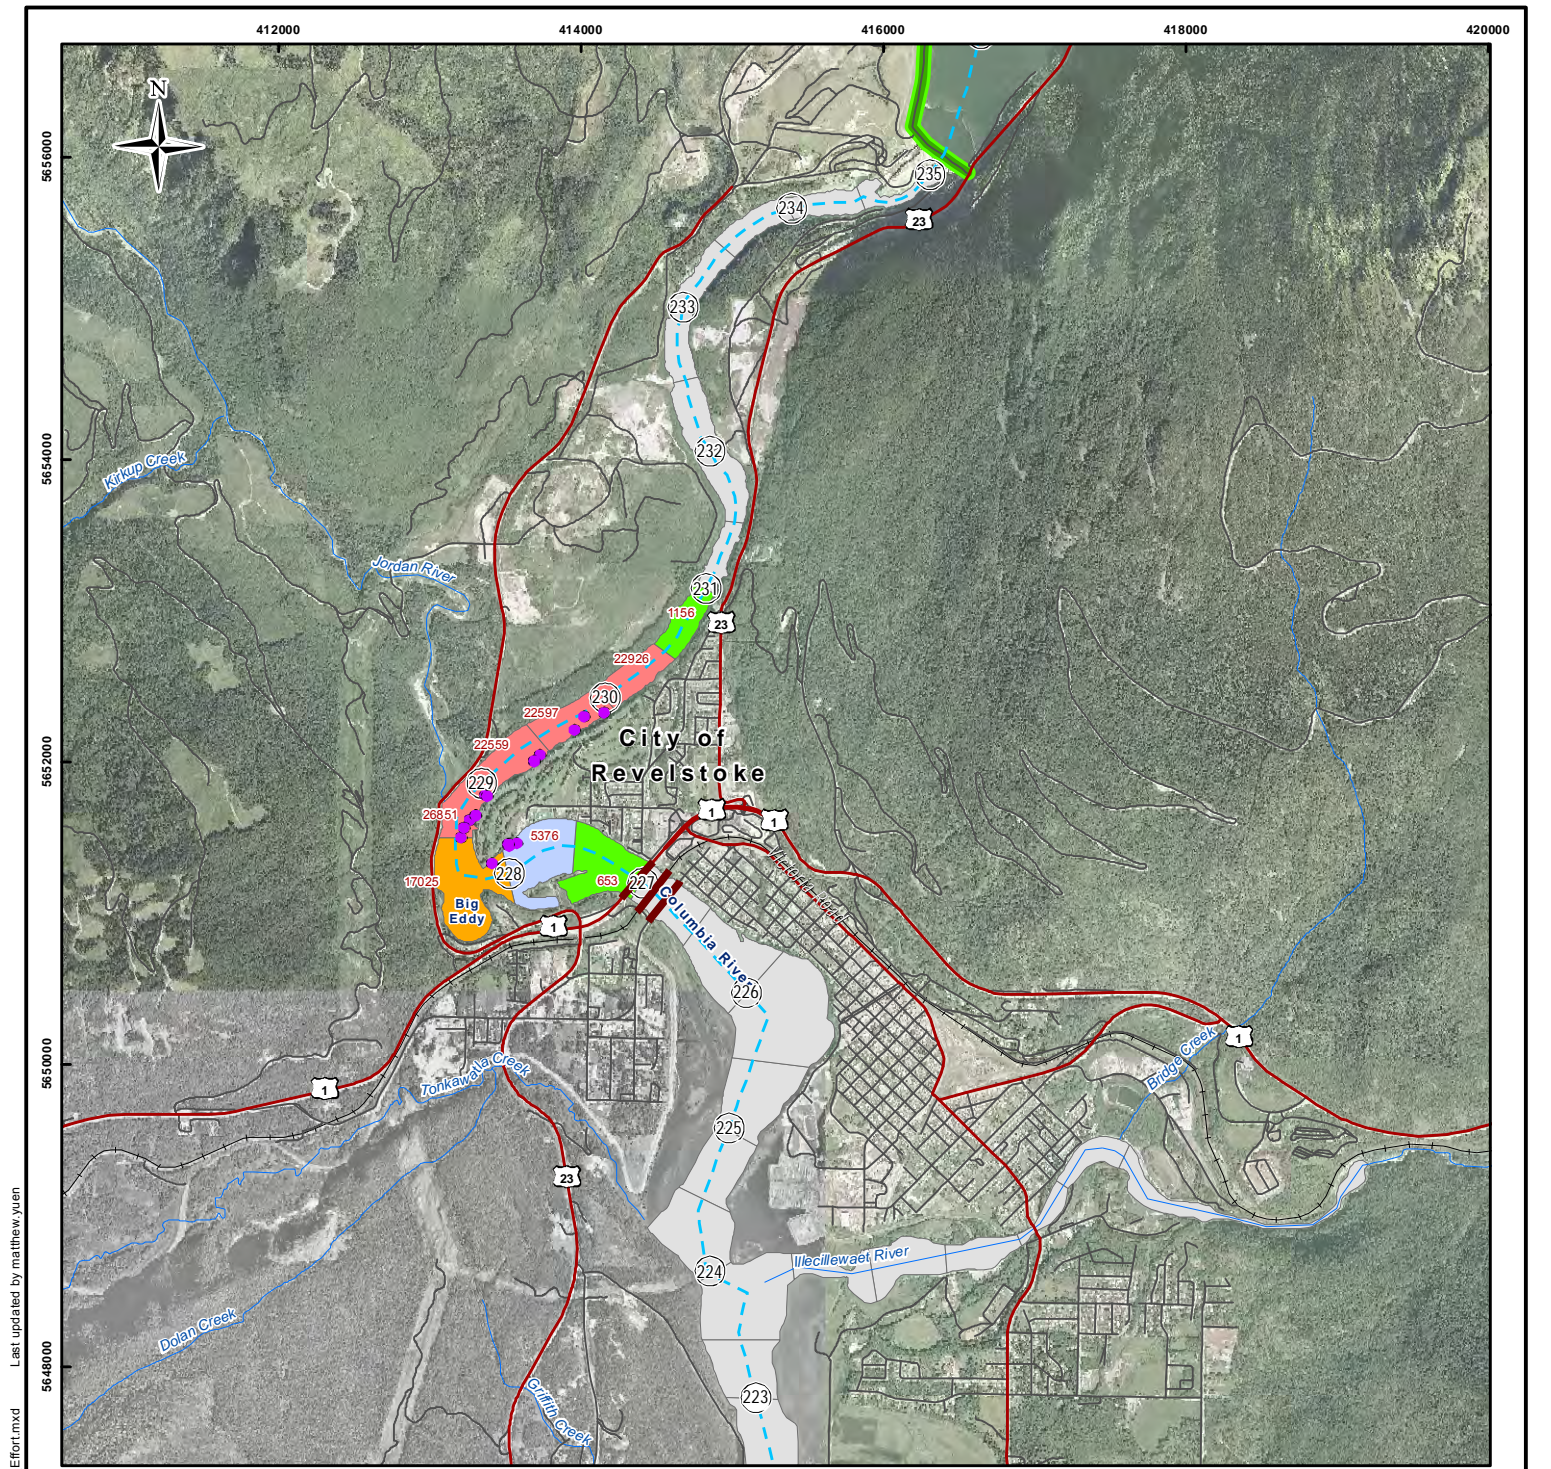

**Table 5: Estimated timing of spawning events based on the developmental stages of captured White Sturgeon eggs and free embryos, 2017.**

Collection Date and Time	Sample Location	Egg/Free Embryo (Number)	Stage	Spot Water Temperature (°C) When Collected	Estimated Spawn Date and Time	Description
26/07/2017 17:05	228.6M	Egg	26	9.7	21/07/2017 17:00	Tail rudiment just separated from yolk sac, lateral plates fuse

### **3.6 White Sturgeon Spawning and Physical Parameters**

A summary of White Sturgeon spawning events and physical parameters observed below Revelstoke Dam during the spawning period (July to September) in years when spawn monitoring was conducted is provided in Table 6. The number of White Sturgeon spawning events recorded between 1999 and 2017 has varied from zero to three (Table 6). Maximum discharges were higher between 2011 and 2017 than in other years when spawning monitoring was conducted. Minimum discharge was also highest since 2011 (i.e., zero discharge did not occur during the spawning monitoring period in 2011 through 2017 and spawning was observed in all those years except 2015; Table 6). Egg stranding surveys were not conducted during the 2017 spawning period because water levels did not expose the area sufficiently to warrant extensive investigations.

**Table 6: White Sturgeon spawning events and physical parameters observed below Revelstoke Dam (July-September) during spawn monitoring programs, 1999 to 2017. Note that spawn monitoring was not conducted in 2002, 2004 and 2005. Table updated from Golder (2012a).**

<sup>b</sup> Data not available.

## **4 DISCUSSION**

The following discussion is structured in accordance with the management questions outlined in the terms of reference for this monitoring program. As mentioned previously, management question 3 (underwater videography) was addressed under a different monitoring program (CLBMON-23B Middle Columbia River White Sturgeon underwater videography feasibility study; Johnson et al. 2009) and will not be further addressed by the present program.

### **4.1 Management Question 1: Where are the primary White Sturgeon incubation sites below Revelstoke Dam?**

Columbia River White Sturgeon typically spawn in high velocity areas that have hydraulic complexity (e.g., turbulence) and coarse substrates (e.g., Parsley et al. 1993 and references cited in Hildebrand and Parsley 2013). Spawning in the mid-Columbia River below Revelstoke Dam has been identified in 11 of 16 years that monitoring has been conducted. It is not surprising that spawning has not been identified every year as the small population estimated for this area (approximately 52 individuals; Golder 2006) could result in mature females not being available every year to spawn given they spawn intermittently and the time between spawning years increases with age. The sex ratio for the population segment below HLK Dam is 1:1 and females are thought to typically spawn once every 3 to 4 years, whereas males may be capable of spawning every year (Hildebrand and Parsley 2013). Assuming a 1:1 sex ratio applies to the mid-Columbia River segment of the population, there may be spawners of each sex available annually but based on the spawning studies conducted below Revelstoke Dam since 1999, the primary White Sturgeon spawning location is a small area and sampling has been consistent across all monitoring years so it is expected that spawning would be detected if it occurred. The area is located within a 2.2 km river section between Km 227.9 and 230.1, which encompasses the area adjacent to the Revelstoke golf course ( Figure 2); REV is located at Km 235 (R.L. & L. Environmental Services Ltd. 2001, Golder 2008, AMEC 2012). White Sturgeon eggs have consistently been documented in this relatively small area although sampling outside this main area has been less frequent. For example, only 1 year of sampling has occurred between the area downstream of the Hwy #1 Bridge (Km 227) and the Illecillewaet River (Figure 7 and Figure Figure 7).

The boundaries of this small spawning/incubation area may shift slightly depending on flows and ALR elevation, but remain relatively similar between years based on results of this work. The eight White Sturgeon eggs and one free embryo collected in 2017 were between Km 227.8 and Km 228.6, within the primary incubation area.

### **4.2 Management Question 2: How do dam and reservoir operations affect egg and larval survival in this area? Specifically, do significant numbers of eggs become dewatered as a result of operations?**

Estimates of egg or larval survival are difficult to calculate for sturgeon species, even in systems where more data are available (e.g. Lake Sturgeon; Caroffino et al. 2010; Duong et al. 2011; Forsythe et al. 2013). Caroffino et al. (2010) estimated overall mortality from the egg stage to larval stage for Lake Sturgeon in the Peshtigo River, Wisconsin, USA at 99% and from egg stage to age-0 juvenile life stage at over 99.9%. In this program, the ability to estimate survival of early life stages was not possible due to the low number of eggs/larvae

that were collected. Based on spawning studies in other areas, successful White Sturgeon egg and larval survival require suitable substrate (gravels/cobbles/boulders) with intermediate interstitial spaces, near bottom water velocity >1 m/s, depth range of 3-25 m and temperature conditions from 10 to 18°C. Conditions modelled within the REV egg incubation area under CLBMON-20 and CLBMON-54 indicate that maximum depths in the thalweg typically range from 5 to 6 m (though they are reduced to 2-3 m during minimum flows); near bottom water velocities of >1.0 m/s are observed approximately 55% of the time during the egg incubation period; and, substrates within the study area consist of coarse materials such as gravels, cobbles and boulders (Hildebrand et al. 2014). Hourly water temperatures in the Revelstoke spawning area are typically below 12°C, with maximum temperatures occasionally reaching 16.1°C (Hildebrand et al. 2014). These findings suggest habitat conditions within the White Sturgeon egg incubation area are suitable for egg and larval survival if habitat requirements are similar to those identified for White Sturgeon in other areas.

It is unknown whether a significant number of eggs become dewatered as a result of operations based on the limited sampling that has been conducted at this time. However the increase in minimum flows and overall discharge capacity has increased the estimated permanently wetted river bed area in the middle Columbia River by approximately 32% when ALR elevation is below 425 m (Dashti et al. 2016). Therefore, this should reduce the severity of potential egg and larval stranding during periods of minimum flow (Hildebrand et al. 2014) and exposure of gravel bars as observed prior to enactment of minimum flows is less likely. During this program, comprehensive egg stranding surveys were conducted twice to investigate dewatering of incubation areas, once in 2009 when minimum REV flow was zero and once in 2011 when minimum REV flow was 145 m<sup>3</sup>/s (Golder 2012). In 2009, seven White Sturgeon eggs were recorded in the 29 m<sup>2</sup> of exposed gravel bar surveyed, which resulted in a density estimate of 0.24 stranded eggs/m<sup>2</sup> and a potential estimated 7,600 stranded eggs over the entire 31,600 m<sup>2</sup> area assuming egg density was the same over the entire gravel bar (Golder 2010). In 2011, no eggs were observed in the 30 m<sup>2</sup> of exposed gravel bar surveyed when approximately 8,000 m<sup>2</sup> of the bar was dewatered (Golder 2012). Between 2012 and 2017, water levels did not expose this area sufficiently during spawning monitoring to warrant extensive investigations (i.e. minimum flows were not observed during the White Sturgeon egg incubation period). In 2017, the ALR backwatered the area over the duration of the spawning and incubation period, no zero flow events occurred and exposure of gravel bars was not observed.

#### **4.3 Management Question 4: What is the most effective method for monitoring spawning of White Sturgeon?**

The most effective method for monitoring White Sturgeon spawning in the mid-Columbia River is a combination of egg mats and drift nets. Other methods for monitoring White Sturgeon spawning in this area have included acoustic telemetry and DIDSON monitoring (Golder 2009, Crossman et al. 2011). Although these methods were effective for observing sturgeon in the spawning area, they were ineffective for monitoring spawning.

During the past 11 years of this program, an average of 125 egg mats have been deployed per spawning season for approximately 21,055 hours which resulted in an average catch-rate of 0.01 eggs/free embryos per 24 mat-hours. In contrast, an average of 38 drift nets

have been deployed per spawning season for approximately 197 hours which resulted in an average catch-rate of 0.13 eggs/free embryos per hour. Although drift nets do have higher catch-rates, they require more frequent inspection and do not monitor continuously like egg mats. Research conducted on sturgeon free embryos has identified a downstream dispersal period following hatch, when endogenous yolk reserves are used (Crossman and Hildebrand 2012). Accordingly, it is important to ensure drift nets are deployed during the period surrounding estimated hatch dates. Parsley et al. 2011 also report that the cooler water temperatures observed in the mid-Columbia River result in free embryos hatching over a protracted period over several days instead of all at once. Therefore, drift nets fished twice per week may have a better chance to overlap with larval downstream dispersal. In 2017, egg mats sampled continuously for approximately 50 days, whereas drift nets covered one third of that time (15 days).

#### **4.4 Management Question 5: Can modifications be made to operations of Revelstoke Dam and ALR to protect or enhance White Sturgeon incubation habitat?**

It is unknown at this time whether additional modifications to REV/ALR operations can be made to protect or enhance White Sturgeon incubation habitat. Flow modifications have already occurred with the addition of REV5 and the implementation of a REV 142 m<sup>3</sup>/s minimum discharge (see Section 4.2). Preliminary information collected during this monitoring program before and after REV5 suggests that recent operational modifications may reduce White Sturgeon egg stranding, and spawning has been observed in six of the seven years since REV5 came online concurrently with the implementation of minimum flow requirements (see Section 4.2).

The REV discharge regime, along with ALR elevation may influence the physical conditions (depth, velocity, substrate and thermal regime) observed at the spawning area. Physical changes observed from REV5 operational modifications include greater diel variation in water level and flows, but there was no evidence that this has led to increased seasonal variation (Plate et al. 2015). In addition, less diel variation in water temperature was observed post-WUP flow, but the change in variation observed (0.1-0.4°C) was not ecologically significant nor was this variation seasonal (Golder 2014, Plate et al. 2014, Plate et al. 2015). Hildebrand et al. (2014) indicated that the results of modelled effects of REV discharge and ALR water levels on velocity, depth and substrate are within the ranges observed in successfully recruiting White Sturgeon populations. In addition, there may be benefits of these minimum flows on benthic invertebrate biomass, since substrates submerged for longer daytime periods had greatest availability of preferred fish food items (Larratt et al. 2017). However, other confounding variables such as duration of daily high flows, ALR backwatering and tributary inflows also influence the total abundance, biomass and diversity of benthic communities (Laratt et al. 2017).

## **5 RECOMMENDATIONS**

The following recommendations pertain to ALR White Sturgeon spawn monitoring activities that may help with data gaps identified for the Columbia River population (UCWSRI 2017; J. Crossman, pers. comm., 2016):

- Continue the same sampling program as 2017 during the 2018 White Sturgeon spawning period. The middle Columbia population is unique in that it has the latest temporal spawning period of all Columbia River White Sturgeon populations. Continuing spawning monitoring will track the timing, frequency and location of spawning events to aid in ongoing research into hypotheses related to recruitment failure for the Upper Columbia White Sturgeon population.
- Transport eggs and/or larvae that are alive to the Kootenay Trout Hatchery for rearing and future release into ALR in order to increase the genetic diversity of the supplemental progeny.
- Collect a tissue sample for genetic analyses from any larvae that are collected dead and not transported to the hatchery. Tissue samples from progeny can identify parental lineage from adult White Sturgeon and allow for estimation of the number of adults spawning in that year.

<sup>1</sup> CPUE = Catch per Unit Effort (number of eggs or free embryos / hour of effort or 100 m<sup>3</sup> of water sampled).

"-" Drift nets set overnight and velocity meter readings could not be determined as meters zero'ed themselves an unknown number of times.
